Numerous classification systems have been developed for thymomas over the years. Most of them are of historical value and have little clinical significance. Rosai and Levine, in 1976, developed a classification based on cellular components of the tumor. It had three subtypes: epithelial, lymphocytic and mixed (lymphoepithelial). In this classification, the epithelial type was considered malignant and the lymphocytic type, benign [15]. In 1985, Marino and Muller-Hermelink proposed another classification, based on thymic site of origin: cortical, medullary and mixed thymomas [16]. Later in 1999, Suster and Moran proposed another classification based on morphologic features of differentiation. Here, they were classified into three types: thymoma, atypical thymoma and thymic carcinoma based on the degree of cellular atypia [17].

The World Health Organization (WHO) attempted to organize the pathological classification of thymic tumors and introduced a new nomenclature which subclassified thymomas into types A, AB, B1, B2, B3 and thymic carcinomas. The fourth edition proposed in 2015 remains the most widely used classification system. Thymomas, regardless of subtype, should be considered as malignant neoplasms. Subtypes A, AB and B1 belong to the relatively benign end of the spectrum with lower incidence of invasiveness, locoregional spread and metastasis. Types B2, B3 and thymic carcinomas are more likely to present with locoregionally advanced or metastatic disease [18]. The presence of invasion through the capsule into the surrounding structures dramatically increases the rate of metastases, particularly to the pleural cavity and lung [19]. This may occur despite a cytologically benign appearance. Thymic carcinomas are rare, aggressive tumors which portend an extremely poor prognosis. They have much higher rates of cellular atypia and genetic imbalance as compared to thymomas.

5.1.2 Staging System

Masaoka et al. proposed a surgical staging system for thymomas in 1981 which was predictive of 20-year survival [20]. It was later modified in 2011 and renamed the Masaoka–Koga staging system [21]. This is currently the most popular clinical and pathological staging system and is endorsed by the International Thymic Malignancy Interest Group (ITMIG). The UICC TNM staging system, which was brought into practice in January 2018, still awaits clinical validation Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 428, Chapter no. 35, Thymus Table: Definition of TNM and AJCC prognostic stage groups which can be accessed at https://emedicine.medscape.com/article/1999313-overview

5.1.3 Presentation

A significant proportion of mediastinal masses are diagnosed incidentally, on routine chest imaging performed for some other reason [13, 22]. The rest, present with symptoms related to local compression, infiltration, paraneoplastic syndromes or rarely metastases. Common presenting symptoms are heaviness in the chest, pain, cough and respiratory symptoms like dyspnea on exertion. When the tumor increases in size it starts compressing/invading adjacent structures and causing symptoms as mentioned in the previous section. In addition to the symptoms commonly caused by anterior mediastinal masses, thymic neoplasms are characteristically associated with a number of systemic syndromes. They may be classified as autoimmune disorders, endocrine disorders, blood dyscrasias and neuromuscular syndromes. A detailed description of all these associations is beyond the scope of this chapter and the discussion will be limited to the most common ones.

Myasthenia gravis is the most commonly associated autoimmune disorder. In one series myasthenia gravis (MG) was the third most common presenting symptom after asymptomatic presentation and chest pain [17]. Around 24% to 40% of thymoma patients develop MG [23], while 15% to 20% of MG patients develop thymoma. MG is caused by the presence of autoantibodies to postsynaptic nicotinic acetylcholine receptors. This manifests as muscle weakness leading to ptosis, diplopia, dysarthria, dysphagia, etc. Severe cases may cause respiratory weakness and crisis. The mainstay of treatment is anticholine esterase mimetic agents like pyridostigmine and immunosuppressive drugs like corticosteroids and azathioprine. In severe cases, intravenous immunoglobulins and plasmapheresis may be used. The role of thymectomy in patients with MG is subject to debate, with varying levels of remission reported. The randomized MGTX trial demonstrated benefit with thymectomy in patients with antibody positive MG without a thymoma, with patients undergoing thymectomy having lower requirement for immunosuppression and decreased hospitalization [24]. However, whether surgery is beneficial in patients with MG and thymoma is unclear.

Pure red cell aplasia (PRCA) is an autoimmune disorder causing anemia due to the absence of red cell precursors in the bone marrow. Around 10% of patients with PRCA may have an associated thymoma, but the incidence of PRCA in a known case of thymoma is very rare [25] Thymectomy helps in remission in only around 30% of patients with PRCA and a thymic mass [20].

Hypogammaglobulinemia is seen in 6% to 11% of patients with thymoma. Both cellular and humoral immunity are affected. Patients usually present with recurrent chest infections or sinusitis. Role of thymectomy in this syndrome is doubtful [26] with very low remission rates, long-term immunoglobulin therapy being the only treatment option.

5.1.4 Investigations

Contrast-enhanced computed tomography (CECT) of the thorax is the preferred investigation for thymic neoplasms. It gives a clear picture about the extent of disease and planes with surrounding structures (Fig. 3). In addition, it provides information about the presence of pleural and parenchymal deposits, the most common sites of metastases. Thymoma classically appears as a homogenous, well defined mass, enhancing with contrast [27]. In most cases, CECT of the thorax provides adequate information to characterize the lesion and decide regarding resectability. In more advanced cases with infiltration of adjacent vascular structures, MRI may be a useful tool [28] (Fig. 4). A few studies have used diffusion-weighted (DW-MRI) [29] and 18-FDG PET CECT [30] to differentiate low- and high-grade thymic neoplasms and have shown good correlation with survival as well (Fig. 5). However, this has yet to prove benefit in clinical practice.

An anterior mediastinal mass with characteristic radiological features of a thymoma presenting with associated syndromes like myasthenia gravis or PRCA does not require histopathological confirmation. In case of any diagnostic dilemma, or in cases which may require multimodality management, it is better to obtain tissue diagnosis before starting treatment. CT-guided biopsy through an extrapleural route is the preferred method.

Anti-acetylcholine receptor (anti-AchR) antibody levels should be checked in all patients with suspected thymic neo-

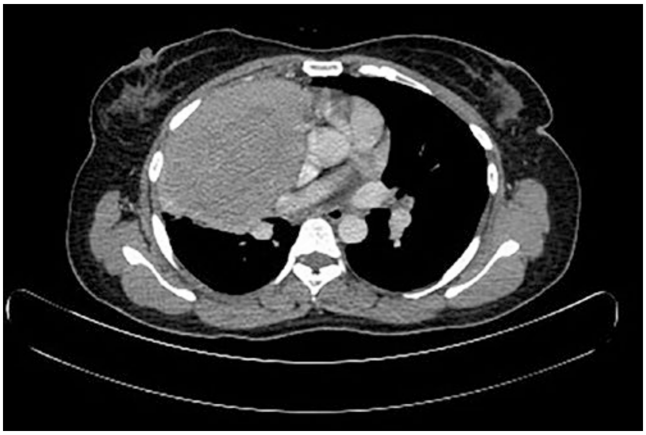

Fig. 3 Thymoma

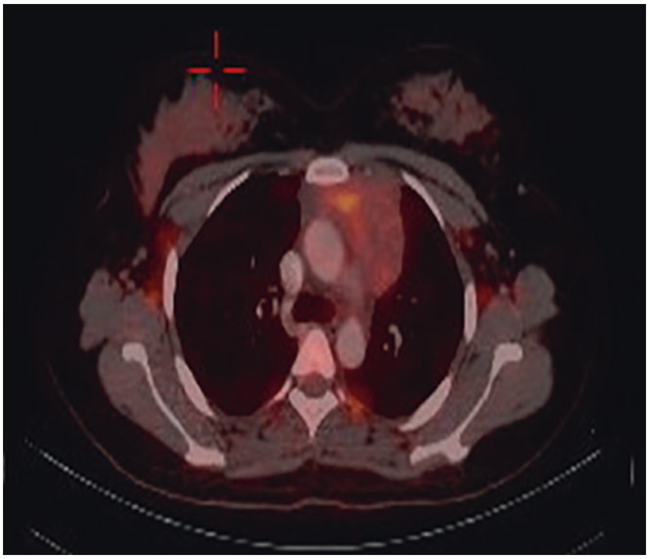

Fig. 5 PET CECT of thymoma showing pleural drop metastasis

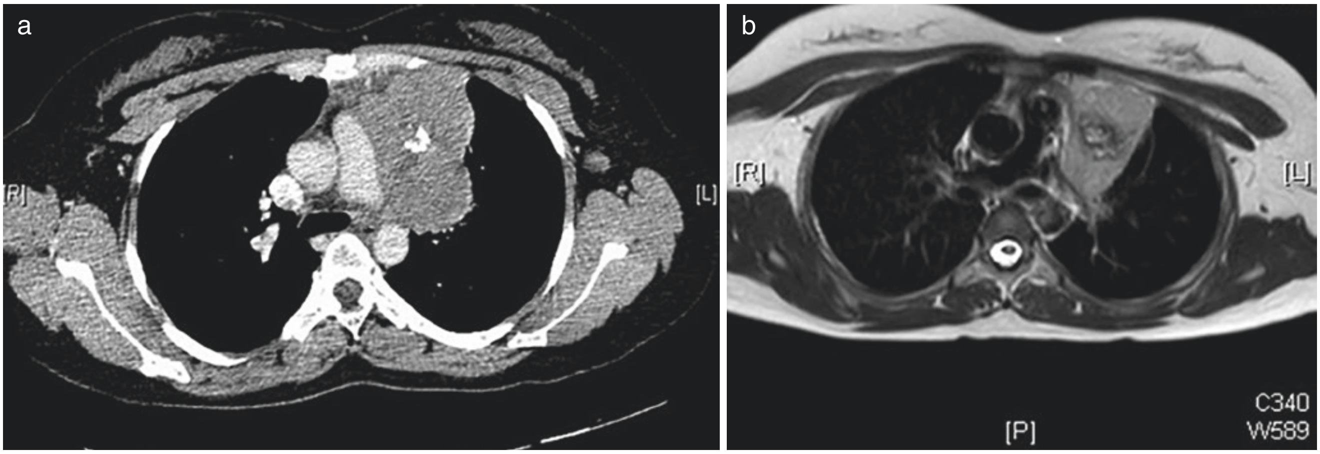

Fig. 4 (**a**) CT scan of thymoma with suspected infiltration of pulmonary conus. (**b**) MRI shows no evidence of infiltration of pulmonary artery

plasms [31]. Presence of antibodies helps in clinching the diagnosis and may help avoid a biopsy. All patients with MG may not have overt symptoms and it is important to diagnose such cases and start medical management before embarking on surgery. Thymectomy in previously undiagnosed cases of MG may cause exacerbation of MG and myasthenic crisis.

5.1.5 Management

Stage I/II

Surgery is the mainstay of treatment for early stage thymoma (Masaoka I/II). In well encapsulated and resectable tumors, primary surgery is the preferred treatment option. The extent of surgical resection involves en bloc resection of the tumor mass with all fibro-fatty tissue anterior to the pericardium between both phrenic nerves bilaterally and from the hyoid to the diaphragm craniocaudally. Dissection of the first echelon of draining lymph nodes, i.e., pericardial, aortopulmonary and paratracheal, is recommended by ITMIG. Completeness of resection (R0) is an important prognostic factor and confers improved survival [32]. Every attempt should be made to resect the tumor without any breach of the capsule, along with the entire thymus and any adjacent structures which are infiltrated. All efforts should be made to preserve the phrenic nerves, at least on one side. Involvement of the phrenic nerve can be predicted by an elevated hemidiaphragm on preoperative imaging and should be kept in mind during surgery, so that extra precautions can be taken to safeguard the contralateral nerve. The traditional approach to thymic surgery has been via a median sternotomy, and it still remains the go-to approach in difficult cases. Minimally invasive approaches, both VATS and robotic are gaining in popularity and several series have shown no difference in R0 resection rates or local recurrence rates between the two approaches [33]. Length of hospital stay is shorter in the minimally invasive surgery group with no difference in major perioperative complications [34].

Stage I thymic neoplasms do not require adjuvant treatment, regardless of histology. Adjuvant treatment in stage II is a matter of debate. Patients with Stage II and R0 resection did not benefit from postoperative radiation therapy (PORT) in the earlier trial [35]. In fact, the Chinese Alliance for research in Thymomas (ChART) showed a detrimental effect of PORT in patients with an R0 resection. However, patients with R+ resection had better overall survival (OS) and disease-free survival (DFS) with PORT [36].

Stage III/IV

Stage III and IV thymic neoplasms require multimodality management. Surgery should be attempted wherever R0 resection is possible. In patients with borderline resectability, induction chemotherapy should be considered. Combination chemotherapy with cisplatin and anthracyclines has shown modest pathological response as well as better R0 resection rates [37]. Whenever multimodality treatment is anticipated in a patient planned for surgery, it is preferable to administer the chemotherapy before surgery in view of the improved tolerability and a higher R0 resection rate. Adjuvant radiotherapy has demonstrated a survival advantage in Stage III and IV thymomas, particularly after a macroscopic complete resection [38]. The ChART trial showed improvement in survival in margin positive resected thymomas [27].

The role of debulking surgery in thymoma is controversial. A number of series and a meta-analysis have shown marginal benefit with debulking surgery over biopsy alone [39, 40]. However, most of these series are retrospective and have an inherent selection bias, making it difficult to draw definitive conclusions. Similarly, the role of surgery in recurrent disease is also questionable with a few series showing marginal benefit with resurgery [41].

In unresectable lesions, concurrent chemoradiation with radiation doses up to 60 Gy can be given [42]. Intensity-modulated radiotherapy (IMRT) with respiratory gating is the preferred technique. Systemic therapy with combination chemotherapy can be attempted in metastatic or recurrent disease [43], although there is no strong evidence in support. A number of targetable mutations like tyrosine kinase (TK), c-KIT and the more recent PD-L1 have been identified in thymic neoplasms [43, 44]. However, early studies have not been able to demonstrate a significant benefit, and further research is warranted.

5.1.6 Prognosis

As in any other malignancy, the two most important outcomes considered after treatment of thymic neoplasms are recurrence and overall survival. As far as recurrence is concerned, the WHO histological type, Masaoka stage, resection status, tumor size and postoperative treatment are important determining factors. In one study, after a median follow up 105 months, a recurrence rate of 1.5% to 7.5% was seen in Masaoka Stage I and II, whereas it was 30% in stage III and 80% in IVa, respectively. B2 and B3 histological types have higher chances of recurrence compared to A, AB and B1 [16]. On multivariate analysis, tumor size more than 4 cm has been found to be an independent factor negatively impacting recurrence-free survival (RFS) [44]. As mentioned in the previous section, the ChART study showed improved recurrence-free survival with radiotherapy after R+ resection and in advanced stages (III/IV). A retrospective analysis of the ITMIG database showed 5- and 10-year survival of 95% and 86% with surgery and PORT in stage II and III thymoma, respectively [45]. In a multi-institutional trial, 5-year overall survival rate after total resection, subtotal resection, and inoperability was 93%, 64%, and 36%, respectively, in stage III and IV thymoma [32].

6 Mediastinal Germ Cell Tumors

Mediastinal germ cell tumors (GCT) are derived from primitive germ cells that fail to migrate completely during early embryogenesis. The mediastinum is the most common extragonadal primary site for GCT. GCTs comprise 10% to 15% of anterior mediastinal masses. They are seen more commonly in males and in the third decade of life.

Although histologically similar to their gonadal counterparts, they have a more aggressive biology and poorer prognosis. When a malignant mediastinal germ cell tumor is diagnosed, primary gonadal GCT must be excluded by scrotal and abdominal examination and a scrotal ultrasound.

GCTs are a heterogeneous group and are classified into benign teratoma, malignant seminoma and nonseminomatous germ cell tumor (NSGCT). Serologic tumor markers like alpha-fetoprotein (AFP), human chorionic gonadotropin (beta-HCG) and lactate dehydrogenase (LDH) are helpful in diagnostic differentiation.

6.1 Teratoma

Benign teratomas are the most common mediastinal GCT and arise from one of the three primitive germ cell layers [46]. Mature teratomas are composed predominantly of ectodermal components like skin, hair or tooth like structures and less commonly mesodermal components like fat, cartilage and bone. Immature and malignant teratomas contain fetal and neuroendocrine tissue and carry a poor prognosis. Rarely, mature teratomas may undergo malignant transformation with a focus of sarcoma or carcinoma.

Mature teratomas occur in children and young adults and are usually asymptomatic. They present as an encapsulated mass in the anterior mediastinum and may protrude to one side of the midline. Radiologically, a uniloculated or multiloculated cystic lesion containing fluid, soft tissue, calcium and/or fat attenuation in an anterior mediastinal mass is a characteristic finding of a teratoma (see Fig. 1). Calcifications are seen in up to 30% of these tumors and they may be focal or rim like. In a small subset of cases mature teratomas may appear as cystic lesions without fat or calcium [5]. Tumor markers are normal in these patients. Complete surgical resection is the treatment of choice [47]. Radiotherapy and chemotherapy play no role in management of teratomas.

6.2 Seminoma

Seminomas are uncommon in their pure form. They are seen in men who are in their second to fourth decades of life. Clinically, patients have dyspnea, substernal chest pain and up to 10% of them present with superior vena cava syndrome [48]. Pure seminomas have normal AFP levels and beta-HCG may be elevated in 10%. Radiologically, seminomas are bulky homogenous masses which usually do not invade locally but metastasize to lymph nodes and calcifications are rare.

Pure seminomas fall under the Intermediate Risk category of the International Germ Cell Consensus Classification and the intent of treatment should be curative even in patients with visceral metastases. These are very radiosensitive tumors and for many years, radiation had been used in the primary setting or adjuvant setting to achieve local control. But, due to large radiation portals and high recurrence rates at distant sites, cisplatin-based combination chemotherapy is currently considered as first line therapy [49].

Small localized tumors may be treated with radiation alone and for locally advanced disease, the most common presentation, the preferred treatment is systemic chemotherapy (cisplatin and etoposide) [50]. The response to chemotherapy is usually excellent, with tumor markers normalizing and even large tumors shrinking dramatically to small plaque like lesions [51]. The role of surgery in the definitive management of seminomas is subject to debate. Although surgery can extirpate the residual disease and give an idea as to the completeness of response to chemotherapy, surgery itself may be technically demanding due to the dense desmoplastic reaction and fibrosis after chemotherapy. Most often, no residual disease is found in the resected mass. Hence, the debate whether it is worthwhile subjects the patient to the morbidity of a technically demanding surgery. Another frequently used strategy in patients with normalized tumor markers is to follow up the residual mass with PET CECT imaging and CT guided biopsy and consider for resection only if there is FDG uptake or biopsy shows residual disease or teratoma [52]. If residual disease is present and deemed unresectable, radiotherapy is the modality of choice, since these tumors are exquisitely sensitive to radiotherapy [53]. Surgical debulking of large seminomas has shown no benefit in improving survival [54].

6.3 Nonseminomatous Germ Cell Tumors (NSGCT)

NSGCTs comprise a diverse group including embryonal cell carcinoma, yolk sac tumors, endodermal sinus tumors, choriocarcinoma and mixed germ cell tumors. These are malignant tumors and are mostly symptomatic, with 80% being metastatic at the time of diagnosis. NSGCT is uniquely associated with hematological malignancies and 20% of them have Klinefelter's syndrome [55]. Tumor markers (AFP, beta-HCG, LDH) are elevated in majority of the cases and are important in establishing a diagnosis. AFP is high in embryonal carcinoma or endodermal sinus tumor.

Radiologically, NSGCTs are large, irregular heterogeneous masses with areas of necrosis, hemorrhage or cyst formation. They invade adjacent structures and may metastasize to lymph nodes and distant organs. Accompanying pleural and pericardial effusions are not uncommon with these tumors.

The initial treatment of NSGCT is cisplatin-based chemotherapy. Various combinations of cisplatin with ifosfamide, vinblastine, bleomycin or etoposide have been studied. Complete remission rates range from 40% to 60% in most series [49, 56, 57]. Four cycles of VIP (vinblastine, ifosfamide and cisplatin) is the preferred regimen over BEP (bleomycin, etoposide and cisplatin) due to increased risk of bleomycin induced pulmonary toxicity in patients with underlying lung disease or in patients requiring thoracotomy or sternotomy for residual lesions [58]. The efficacy of both the regimen appears to be similar. Surgical resection for any residual mass, which could represent either a teratoma or residual disease, is indicated when the tumor markers normalize. Salvage chemotherapy is administered to patients with persistently high tumor markers.

Primary mediastinal NSGCTs fall into the poor risk category of International Germ cell Consensus classification and have 40% to 50% 5-year survival which is lower compared to their gonadal counterparts.

Growing teratoma syndrome is a rare clinical phenomenon seen in patients with NSGCT at the primary or metastatic sites. It was described by Logothetis in 1982 [59] as masses of NSGCT enlarging despite systemic chemotherapy and normalization of tumor markers, with exclusive presence of mature teratoma and no viable germ cell component. The incidence ranges from 1.9% to 7.6% in all NSGCT [60], with the most common site being retroperitoneum. In primary mediastinal NSGCT, growing teratoma syndrome is rare with one series reporting 2.6% [61]. Early diagnosis of this clinical entity is important due to the complications caused by mechanical compression of the surrounding structures by the enlarging mass. As it comprises mainly mature teratomatous component, chemotherapy or radiotherapy is ineffective. Complete surgical resection is the treatment of choice and carries excellent prognosis. Recurrence rates following complete resection are low, around 4%, whereas with incomplete resection, recurrence ranges around 83% [62].

7 Posterior Mediastinal Tumors

A majority of posterior mediastinal tumors are of neurogenic origin. Most arise from the sympathetic trunk or intercostal rami and are Schwannomas or neurofibromas. In general, neurogenic tumors are benign with approximately 30% associated with von Recklinghausen syndrome [63]. Rarely, Schwannomas may arise from the vagus nerve in the middle mediastinum [64]. Most of them are asymptomatic and are diagnosed incidentally. However, they may erode adjacent osseous structures and extend through vertebral foramina forming dumbbell tumors. Symptoms, when they occur, are due to compression of the tracheobronchial tree, nerve roots or the chest wall. The incidence of malignancy in neurogenic tumors is rare with most of them occurring in the background of neurofibromatosis [65].

The initial radiological investigation of choice is CECT thorax with characteristic features obviating the need of a biopsy. MRI may help in better characterization and in identifying intraspinal extension or neural involvement (see Fig. 2).

Asymptomatic and small tumors with no significant compression over adjacent structures may be observed. In symptomatic patients, complete surgical resection without breach of the capsule is the treatment of choice. A minimally invasive approach is preferred where possible. In case of intraspinal extension, a combined approach along with a neurosurgical team may be required. While the results of surgery are generally good, the prognosis after surgery for malignant tumors remains poor [66]. Most require postoperative radiotherapy, but there is no definite evidence of benefit with adjuvant chemotherapy [63].

Esophageal Cancer

Apurva Ashok, Sabita Jiwnani, George Karimundackal,
and C. S. Pramesh

Abbreviations

ADC	Adenocarcinoma
BE	Barrett's esophagus
CECT	Contrast-enhanced computed tomography
DLCO	Diffusion capacity of lung for carbon monoxide
EBRT	External beam radiation therapy
EMR	Endoscopic mucosal resection
EUS	Endoscopic ultrasonography
FEV1	Forced expiratory volume in first second
GERD	Gastroesophageal reflux disease
HDI	Human development index
HPV	Human papilloma virus
ILRT	Intraluminal brachytherapy
IMRT	Intensity-modulated radiation therapy
LTA	Left thoracoabdominal
MIE	Minimally invasive esophagectomy
NACRT	Neoadjuvant treatment with chemoradiotherapy
NACT	Neoadjuvant treatment with chemotherapy
NART	Neoadjuvant radiotherapy
PET	Positron emission tomography
PFT	Pulmonary function test
SCC	Squamous cell carcinoma
THE	Transhiatal esophagectomy
UGIE	Upper gastrointestinal endoscopy

1 Introduction

Esophageal cancer ranks seventh in terms of incidence worldwide with 572,000 new cases and sixth in overall mortality [1]. There has been a steady increase in new cases of esophageal cancer with approximately 70% occurring in men. Highest rates of incidence have been reported from East Asia followed by Southern Africa [2]. Majority of them lie in the "esophageal cancer belt" which extends from North-East China to the Middle East. Adenocarcinoma (ADC) and squamous cell carcinoma (SCC) being the most common histological types of esophageal cancer vary in their distribution, and melanoma, small cell carcinoma, sarcoma or lymphoma constitute a small proportion (1%–2%) of these cancers. In countries with a high human development index (HDI), there is higher incidence of adenocarcinoma of the esophagus, whereas in low HDI countries like India, SCC is more common [3]. The incidence peaks in the sixth decade in most parts of the world. In India, esophageal cancer is the sixth most common cause of cancer related death and the North-East region of India reports the highest incidence [4].

2 Risk Factors

Esophageal squamous cell carcinoma and adenocarcinoma differ in their epidemiology, pathogenesis and biological behavior. Pathophysiology of SCC is believed to be a precursor lesion of epithelial dysplasia progressing to severe dysplasia to carcinoma in situ and finally to invasive carcinoma [5]. ADC, in contrast, is usually seen in patients with persistent gastroesophageal reflux disease (GERD) and intestinal metaplasia (metaplasia–dysplasia–neoplasia sequence) [6].

Major risk factors for SCC are tobacco/smoking, alcohol consumption, poor nutritional status, caustic injury, consumption of hot beverages and possibly human papilloma virus (HPV) infection. Smoking and alcohol have a synergistic effect and is related to carcinogenic ingredients like polycyclic aromatic hydrocarbons, nitrosamines, aldehydes and

their derivatives [7]. Local risk factors in India like betel quid chewing, hookah, snuff, hot salted tea and red chilies have been implicated in carcinogenesis. HPV is reported to be associated with SCC in high incidence areas but exact role in pathogenesis needs further study [8].

The risk factors of ADC include obesity, GERD, cigarette smoking, Barrett's esophagus (BE), male sex and diet low in vegetables and fruit. BE is strongly associated with GERD and the risk of developing ADC is 0.1–0.5% per year. The risk increases with increasing length of Barrett's [9]. Deficiency of micronutrients such as vitamin A, E, C, riboflavin, zinc and selenium also contribute to development of esophageal cancer.

Genetic alterations such as mutations in p53, cyclin D1 and cell cycle regulatory proteins have been associated with development of esophageal cancer [10]. In high incidence areas like China, genetic susceptibility (familial aggregation) to ESCC has been reported [11]. Tylosis, a hereditary disorder, involving hyperkeratosis of the palms and soles, has a high risk of esophageal cancer [12].

3 Clinical Presentation

Progressive dysphagia or odynophagia are the most common presenting symptoms of esophageal cancer. Unintentional weight loss (more than 10% of normal body weight in 6 months) is seen mostly in ESCC patients and is not a frequent finding in EADC. Some symptoms develop late in the course of the disease like chest pain or back pain when swallowing, supraclavicular lymphadenopathy, hoarseness from recurrent laryngeal nerve involvement, cough or sudden onset of hiccups. Screening endoscopy in Japan and Korea picks up early asymptomatic disease, but in India, disease is mostly locally advanced at the time of presentation.

4 Diagnosis and Staging

1. Barium swallow—Though barium swallow is sometimes used as the initial assessment tool in peripheral hospitals, its clinical utility is questionable. A normal barium swallow does not preclude the need for an upper gastrointestinal endoscopy (UGIE) as early mucosal lesions may get missed with a barium swallow; in an abnormal barium swallow, an UGIE would be required in any case to map the disease and biopsy the lesion. Therefore, it provides no additional information, nor does it change the management in any way. It is therefore not indicated in patients with suspected esophageal cancer.
2. Upper GI endoscopy—This remains the preliminary investigation of choice for patients with dysphagia. The endoscopy should be thorough, and should have a clear mention of the location of the tumor, extent of involvement, level of the cricopharynx and the gastroesophageal junction. A minimum of 6 to 8 biopsies is recommended to minimize the need for repeat endoscopies. Brush cytology has shown a correlation of 80% in most studies and may be explored for screening or rapid diagnosis, and is of value in predominantly stricturous lesions [13].
3. Radiology.
   (a) Contrast-enhanced computed tomography (CECT) thorax and abdomen—A CECT scan is the initial imaging modality to stage esophageal cancer. It is effective in assessment of the T stage, invasion of surrounding structures and screening liver, and lung for distant metastases. However, it is less accurate for nodal assessment.
   (b) PET-CT—^{18}FDG positron emission tomography (PET) provides incremental staging information, especially when combined with CT scan. The diagnostic accuracy increases to 92% when both modalities are used. Distant metastases are best detected by PET-CT and it can change the clinical management in a significant number of patients [14]. It should be included routinely in diagnostic algorithm of esophageal cancer staging. PET-CT has also shown encouraging results in assessing the response to induction therapy [15]. However, it might be less effective in assessment of response to neoadjuvant chemoradiation than to neoadjuvant chemotherapy.
4. Endoscopic ultrasonography (EUS) is used for refining locoregional staging. It is superior to CECT with regards to assessment of depth of tumor invasion and regional nodal status. It helps to delineate various layers of the esophageal wall and has high sensitivity and specificity for defining the T stage in esophageal cancer. However, with the acceptance of neoadjuvant chemoradiotherapy or chemotherapy as the treatment of choice in localized esophageal cancer, the role of EUS is restricted to very early disease (where T1N0 cancers may be operated without neoadjuvant treatment) or in patients with borderline resectability. Advanced (T4) disease is detected better with EUS than early (T1) lesions. High-frequency probes (20–30 Mhz) increase the accuracy for T1 and T2 tumors [16]. EUS has the advantage of the possibility to perform FNA during the procedure. Sensitivity and specificity of EUS improves from 85% to 96% in evaluating N stage with addition of FNA from nodes [17]. EUS may not be technically feasible in stenotic lesions. Its role in restaging after neoadjuvant therapy is limited, as it cannot reliably differentiate between fibrosis and residual or recurrent disease.
5. Bronchoscopy is essential for assessing trachea-bronchial tree involvement in upper and middle third esophageal disease prior to starting treatment, especially in patients with bulky disease on axial imaging. It is more sensitive than conventional imaging modalities to diagnose early involvement of the tracheobronchial tree.

6. Minimally invasive staging—The role of laparoscopy and thoracoscopy in preoperative staging is being investigated. Some studies have shown that detection of advanced disease (<1 cm lesions) and positive lymph nodes, is better with these modalities as compared to noninvasive staging [18]. Staging laparoscopy has a role in the staging algorithm for esophageal and gastroesophageal adenocarcinoma, picking up occult metastases in 20% to 40% of the patients even after comprehensive radiological staging [19].
7. Tumor markers—Various biomarkers including immunohistochemical markers, serum tumor markers and miRNA markers have been evaluated in diagnosis and prognosis of esophageal cancer. CEA, p53 antibody, SCC-Ag, Cyfra21–1 and VEGF-C have been studied for their potential in aiding diagnosis of esophageal carcinoma, but they are not yet recommended for use in routine practice [20].
8. Functional evaluation with echocardiography and pulmonary function test (PFT) is useful in most patients planned for radical treatment. Forced expiratory volume in first second (FEV1) and diffusion capacity of lung for carbon monoxide (DLCO) are important predictors of pulmonary complications and values of less than 40% are associated with high risk.

5 Staging

The eighth edition of American Joint Committee on Cancer (AJCC) staging of the esophageal cancers came into effect in 2017 and included certain changes from the seventh edition: [21].

- Separate classifications for clinical (cTNM), pathologic (pTNM) and postneoadjuvant (ypTNM) stage groups. The rationale for this addition was the absence of equivalent categories peculiar to the post neoadjuvant state (ypT0N0-3 M0 and ypTisN0-3 M0) and markedly different survival profiles. Adenocarcinoma and squamous cell carcinoma are classified separately in clinical and pathological staging, but ypTNM groupings are identical for both cell types.
- Subclassification of T1 into 1a and 1b.
- Definition of subtype (squamous/glandular) and grading of cancers (% in glands).
- Definition of location: Epicenter of the tumor is used to define the location in eighth, edition whereas it was the upper edge of the cancer in seventh edition.
- Redefinition of gastroesophageal tumors: Adenocarcinomas with epicenter ≤2 cm into the gastric cardia will be staged as esophageal cancers and those extending further (>2 cm) will be staged as stomach cancers.

With the new staging system, groups are more homogenous with respect to prognosis and separation of survival curves. However, for future staging, more refinement in terms of (1) integration of genomics; (2) precision cancer care with targeted therapy; and (3) pathological staging of endoscopically resected cancers are planned to be explored.

6 Patient Optimization

A detailed nutritional assessment and rehabilitation for all patients is part of the initial management of esophageal cancer. Patients with pronounced dysphagia are often malnourished, especially in those with squamous esophageal cancer. Enteral feeding is the preferred route of choice for nutritional supplementation. Endoscopic or fluoroscopic-guided nasogastric tube insertion may be needed for severely dysphagic patients (grade III/IV) at risk of malnutrition.

Pulmonary rehabilitation should be initiated early in the management of esophageal cancers. It is necessary for all patients planned to be treated with radical intent and those with compromised lung function. Incentive spirometry exercises and adequate rehabilitation, significantly reduces the rate of pulmonary complications. Cessation of smoking must be stressed in pretreatment counseling.

7 Management

A multidisciplinary team approach is recommended for treatment of esophageal and gastroesophageal (GEJ) cancers. Standard of care for locoregionally advanced esophageal cancers (cT3,4/N+) is a multimodality approach with integration of chemotherapy, radiotherapy and surgical resection, whereas a single modality may be sufficient for early disease (cT1,2 N0).

Factors deciding treatment include:

- Location of the disease.
  - Cervical esophageal cancer and upper third lesions within 5 cm of cricopharynx are preferred to be treated with concurrent chemoradiation or radical radiotherapy [22].
  - For resectable middle third, lower third and GEJ cancers, surgery is the most effective treatment.
- Stage of the disease.
  - Early stage cancers (T1–2, N0) are treated with single modality—either endoscopic resection (EMR/ESD for very early disease) or surgery.
  - Locally advanced disease (T3–4a or N+) receive multimodality treatment-neoadjuvant therapy followed by surgery or definitive chemoradiation.

- Patients with metastatic disease require palliation of symptoms with either palliative radiation, esophageal stenting or palliative chemotherapy.

7.1 Endoscopic Treatment

Early superficial esophageal cancers may be managed with either endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD). Indications for endoscopic treatment include (1) Intramucosal lesion (T1a); (2) Diameter of lesion less than 2 cm or less than one-third of the circumference of the esophagus; (3) Absence of nodal involvement [23]. EMR constitutes elevation of the lesion, placement of a metal wire snare and resection using high-frequency diathermy whereas, in ESD, the mucosa is excised using a high-frequency diathermy knife, and dissection is done in the submucosal plane beneath the lesion. An ideal candidate for EMR or ESD would be a T1a well-differentiated lesion, less than 2 cm in diameter, with no ulceration, no lymphovascular or nodal involvement. In these selected cases, endoscopic treatment is gaining equal cure rates in specialized centers [24]. pT1a and pT1b tumors are associated with low risk of nodal metastases (1% and 3%, respectively) and it is assumed that ESD and EMR can achieve similar outcomes as with open surgical resection. Local recurrence rates are high in cases of positive margins or piecemeal resection. Endoscopic surveillance at 6–12 monthly intervals is desirable to detect residual or recurrent tumor and metachronous lesions.

7.2 Surgery

Traditionally, the standard treatment for resectable esophageal cancers is esophagectomy. However, survival is not satisfactory with surgery alone although there have been advances in new surgical techniques and perioperative care. Now, surgery is part of the multimodal treatment approach to improve outcomes.

Indications of surgery include:

(a) Early stage disease (cT1/T2, N0).
(b) Locally advanced disease (T3/T4a, N+) after neoadjuvant treatment.
(c) Residual disease or local recurrence after definitive chemoradiation (salvage esophagectomy).

Principles of surgery are:

(a) To achieve free proximal and distal margins longitudinally and negative circumferential resection margins (CRM). While conventionally a 5-cm margin longitudinally was considered necessary, two retrospective studies have shown that a proximal margin of >3 cm does not yield further survival advantage [25]. A positive CRM is associated with poor prognosis in esophageal cancer patients but the benefit of adjuvant therapy in such setting is still unclear [26, 27].
(b) To perform adequate lymphadenectomy. There is increasing evidence that the number of lymph nodes dissected is an independent prognostic factor after esophagectomy. Traditionally a standard (infracarinal) two-field lymphadenectomy is recommended for most patients with esophageal cancer; in patients with supracarinal nodal involvement, more extensive lymphadenectomy (three field/total mediastinum) may be considered. However, evidence supporting their routine use is lacking.

7.3 Surgical Approach (Table 1)

Surgical approach for esophagectomy depends on the location of tumor, extent of lymphadenectomy planned and expertise of the operating surgeon. The procedure should be least morbid while oncological resection is not compromised.

- For lesions involving upper third and cervical esophagus, surgery is reserved for residual or recurrent disease post chemoradiation and it would entail an extensive procedure of total laryngo-pharyngo-esophagectomy with permanent tracheostomy.
- For lesions involving the middle and lower third of the esophagus, transthoracic esophagectomy with cervical esophagogastric anastomosis is preferred as it provides good access for lymphadenectomy and resection of primary.

Table 1 Types of surgical approach

Surgical approach	Incision	Anastomosis
Transthoracic esophagectomy (TTE)	3 incisions • Laparotomy • Posterolateral thoracotomy • Left supraclavicular	Neck
Transhiatal esophagectomy (THE)	2 incisions • Laparotomy • Left supraclavicular	Neck
Ivor Lewis esophagectomy	2 incisions • Laparotomy • Posterolateral thoracotomy	Thorax
Left thoracoabdominal approach (LTA)	1 incision • Oblique incision extending from abdomen into left thorax	Thorax

- For lesions involving the esophagogastric junction, different approaches may be used like transhiatal esophagectomy (THE), left thoracoabdominal (LTA), Ivor Lewis or transthoracic esophagectomy.

The Ivor Lewis esophagectomy and McKeown procedure (TTE) include a posterolateral right thoracotomy through the fifth intercostal space followed by an esophageal resection with mediastinal and abdominal D2 lymphadenectomy. In TTE and THE, the anastomosis is in the neck, whereas in LTA and Ivor Lewis esophagectomy, the anastomosis is intra thoracic. The procedures involving a thoracotomy (TTE, LTA and Ivor Lewis), allow better clearance of lymph nodes; however, they are also associated with higher rates of pulmonary complications. A randomized trial comparing THE and TTE for adenocarcinoma of the esophagus showed better lymph nodal harvest and trend toward improved long-term survival with TTE but there was increased incidence of pulmonary complications and no significant difference in median or disease-free survival when compared to THE [28]. Similarly a Japanese randomized trial comparing THE with LTA for GEJ tumors failed to show a survival advantage with left thoracoabdominal approach [29]. Two meta-analyses comparing transhiatal to transthoracic esophagectomy showed no difference in disease-free or overall survival; however, most studies in the meta-analyses were retrospective or prospective case series with few randomized trials [30, 31].

Minimally invasive esophagectomy (MIE) with a combined thoracoscopic and laparoscopic approach has been increasingly adopted in recent times to decrease the morbidity and mortality of open esophagectomy. There are three different positions for MIE—prone, lateral and semiprone, based on the surgeon's preference. In a systematic review of studies, morbidity (in terms of blood loss, hospital stay, total complication rate and pulmonary complications) was lower with MIE when compared with open esophagectomy, although all the studies assessed were retrospective [32]. Another prospective, multi-institutional study on MIE, found the stage specific survival to be similar between both the groups [33]; however, it was difficult to fully assess the oncological outcomes of MIE without long-term follow-up. A multicentric, randomized trial comparing open versus MIE demonstrated a significant reduction in pulmonary complications with MIE group [34]. Another randomized trial compared a hybrid minimally invasive approach (laparoscopic abdominal mobilization and open right thoracotomy) with a completely open TTE. The trial confirmed the lower incidence of postoperative complications, mainly pulmonary complications; surprisingly, there was a strong trend (statistically not significant) toward improved overall and disease-free survival in the hybrid MIE arm [35]. Robotic esophagectomy was first started in Netherlands in 2003 and is subsequently being performed in specialized centers across the globe. A case series from Netherlands demonstrated comparable results of robotic esophagectomy to published literature on open surgery, with regards to lymph node yield, extent of resection and survival [36]. The randomized ROBOT trial [37] compared open esophagectomy to the robot-assisted procedure and found overall fewer postoperative complications, decreased blood loss, pulmonary complications, cardiac complications and lower pain. The functional recovery and quality of life measures were also improved with robotic surgery. However, the benefits of robotic esophagectomy over thoracolaparoscopic esophagectomy are uncertain.

7.4 Extent of Lymphadenectomy

Lymph nodal status is one of the most important predictors of survival. The AJCC staging system categorizes regional disease as all periesophageal nodes extending from the lower cervical nodes down to the celiac axis. A minimum lymph node harvest of 15 (12–18) is recommended for adequate staging [38]. In esophagectomy, lymph nodal dissection is most commonly divided into three fields—(1) abdominal field with gastrohepatic and D2 nodes; (2) intrathoracic field with periesophageal, infracarinal nodes and superior mediastinal nodes up to the thoracic inlet; (3) cervical field with nodes along recurrent nerves, supraclavicular and lower deep cervical nodes. Rather than defining the number of lymph nodes to be dissected or the therapeutic ratio, especially in the era of neoadjuvant therapy, template dissection should be attempted [39]. Types of lymphadenectomy are presented in Table 2.

Three field lymphadenectomy (3F) showed improvement in survival without significant increase in complications or mortality in earlier studies [40, 41]. However, most reported studies had small numbers or historical controls. A meta-analysis in 2014 (2 RCT and retrospective studies) demonstrated increased rate of complications (recurrent nerve palsy and anastomotic leakage) with 3F when compared to two field (2F) dissection but improved overall survival [42]. The confounding factor of stage

Table 2 Types of lymphadenectomy

Type of lymphadenectomy	Nodal fields resected
Standard two-field lymphadenectomy	Abdominal field + infracarinal thoracic field
Extended two-field lymphadenectomy	Right superior mediastinal clearance + standard two-field
Total mediastinal lymphadenectomy	Bilateral supracarinal clearance + standard two-field
Three-field lymphadenectomy	Abdominal field + total mediastinal field + cervical field

migration due to extensive lymph node dissection could have shown apparent improvement in survival. In the east (Japan), 3F lymphadenectomy is routinely practiced with all esophagectomies; however due to lack of conclusive evidence and a recent RCT demonstrating no significant improval in survival with 3F over 2F lymphadenectomy [43], it is not recommended in the management guidelines of the west. The advantage of 3F over conventional 2F remains speculative and could be answered by ongoing randomized trials [44, 45].

7.5 Surgical Reconstruction

The stomach is the preferred conduit for reconstruction due to its good vascular supply and single anastomosis to restore continuity. Colon or jejunum are the other alternate options. Pyloric drainage procedure in case of stomach conduit has shown to decrease aspiration and hence pulmonary complications [46].

Route of reconstruction—The posterior mediastinum or the retrosternal route are the two options and both have shown similar perioperative outcomes and conduit function [47].

Anastomosis—Stapled or handsewn (end to end) anastomosis in the neck or intrathoracic location have shown similar leak rates but the stricture rate is high with circular staplers [48].

7.6 Neoadjuvant Therapy

Locally advanced esophageal cancers (T3–4/N0 and T1–4/N+) are treated with neoadjuvant therapy followed by surgery as part of multimodal approach. Neoadjuvant treatment with chemotherapy (NACT) or chemoradiotherapy (NACRT) have been evaluated in multiple studies. Neoadjuvant radiotherapy (NART) alone, has not been shown to be beneficial.

- *Preoperative chemoradiation*—Meta analyses comparing NACRT with surgery to surgery alone has reported improved 3 year survival and reduced locoregional recurrence [49, 50]. However, there was increased morbidity and mortality associated with combined treatment. The randomized CROSS trial and NEOCRTEC trial comparing NACRT followed by surgery to surgery alone showed significantly improved survival (49.4 versus 24 months), 92% R0 resection rate and improved pathological response in the neoadjuvant group, while the postoperative complication profile was similar in both groups. The CROSS protocol constituted radiation of 41.4 Gy/23 fractions over 5 weeks with concurrent weekly chemotherapy (paclitaxel 50 mg/m^2 and carboplatin at area under the curve of 2 mg/mL/min) [51]. The long-term results of the CROSS trial confirmed the overall survival advantage of NACRT in all subgroups and also improved local and distant recurrence rates [52].
- *Preoperative chemotherapy*—Multiple meta-analyses of NACT trials have shown that preoperative chemotherapy followed by surgery appears to offer an absolute 2 year survival advantage ranging from 4% to 11% for both adenocarcinoma and SCC, when compared with surgery alone for resectable esophageal cancer [53]. Chemotherapy regimens commonly used are 5FU/Cisplatin and ECF (Epirubicin, 5FU and Cisplatin) [54]. The Medical Research Council (MRC) trial of 802 patients demonstrated that two cycles of cisplatin and 5-fluorouracil in the neoadjuvant setting improved survival without additional adverse events [55]. Perioperative chemotherapy was evaluated in the MAGIC trial (ECF regimen) [54] and more recently the FLOT 4 study (DOF regimen) [56] in gastric and GEJ adenocarcinoma. Both the trials have shown significantly better overall survival as well as progression-free survival.
- A meta-analysis evaluated NACRT and NACT in esophageal carcinoma, and found strong evidence for absolute survival benefit with both forms of neoadjuvant therapy over surgery alone; however there was no clear advantage of NACRT over NACT [57].

7.7 Adjuvant Therapy

Few studies in patients with esophageal cancer treated with primary surgery have evaluated the role of adjuvant therapy; theoretically, this benefit is likely to be highest in patients with metastatic nodal disease or margin positivity on histopathology. So far, none of these studies have shown a clear survival benefit.

- *Postoperative radiotherapy*—Currently, the only indication of adjuvant radiation is positive margins or residual disease. Adjuvant radiation without chemotherapy has not shown benefit consistently in clinical trials.
- *Postoperative chemotherapy*—Adjuvant chemotherapy is beneficial in patients with nodal disease in adenocarcinoma of the esophagus. Perioperative (three cycles pre and three cycles postoperative) chemotherapy for lower esophageal and GE junction cancers, has been shown to be beneficial as trials have demonstrated both disease-free and overall survival advantage [54, 55]. However, a phase III study by Japanese Clinical Oncology Group (JCOG) reported no difference in overall survival and only a small benefit in disease-free survival [58]. Postoperative adjuvant nivolumab for patients with resid-

ual pathological disease after neoadjuvant chemoradiation followed by surgery in esophageal SCC has shown significantly better disease free survival (CheckMate577 trial) and has been recommended in the latest NCCN guidelines.

- *Postoperative chemoradiotherapy*—Adjuvant chemoradiotherapy may be considered in patients who have not received neoadjuvant treatment with lower third and GEJ adenocarcinoma patients based on results from the Intergroup INT0116 trial [59].

7.8 Definitive Radiation/Chemoradiation

The nonsurgical curative option, evaluated for unresectable esophageal cancers and medically inoperable patients, is definitive chemoradiation. It is also the treatment of choice for upper third esophageal cancers. Earlier studies looked at radiotherapy alone as primary treatment, but were found to have poor outcomes and high local failure rates. Following this, combined modality of concurrent chemoradiation (50 Gy with Cisplatin/5FU) was tested in RTOG 85–01 trial, which reported better overall survival when compared to 64 Gy radiotherapy alone [60]. These results were similar for both SCC and adenocarcinoma and it formed the precedent for accepting definitive chemoradiation as a curative treatment option for locally advanced unresectable esophageal cancers. However, as the local failure rates remained high, dose escalation was evaluated in Intergroup (INT-0123) trial, where increasing the dose of radiation from 50.4 Gy to 64.8 Gy in concomitant chemo radiotherapy setting did not result in improved survival [61]. The most commonly used regimen is 60–64 Gy/30–32 fractions over 4–5 weeks with conventional fractionation and 4 cycles of cisplatin (75–100 mg/m^2 on day 1) and 5-fluorouracil (750–1000 mg/m^2/day × 4 days). A margin of 5 cm above and below the primary tumor with a radial margin of 1–1.5 cm is recommended to account for subclinical disease spread and periesophageal nodes.

Intensity-modulated radiation therapy (IMRT) is a modern technique which can be used to deliver higher doses of radiation, protecting the surrounding vital organs like the heart and lung and thereby having more tolerable adverse effects. A retrospective analysis has shown reduced toxicity profile with IMRT and improved survival [62].

Another method to escalate radiation dose is intraluminal brachytherapy (ILRT) which is used as a boost to external beam radiation (EBRT). A brachytherapy catheter with a diameter of 6 to 10 mm is placed endoscopically in the esophageal lumen and a dose of 5–10 Gy per fraction in 1 to 4 fractions is delivered in addition to 50 Gy EBRT [63]. Treatment related fistulas are a common adverse effect; hence, patients need to be selected appropriately.

7.9 Palliative Treatment

Patients with advanced, metastatic esophageal cancer need to be managed with the goal of prolonging survival and maximizing their quality of life. Pain and dysphagia are two most common symptoms to palliate. Pain may be managed with narcotics (both short acting and long acting) and local radiotherapy in case of bone metastases. Palliation options for dysphagia include (1) Esophageal self-expanding metallic stent; (2) EBRT; (3) ILRT; (4) Feeding tubes; or a combination of these methods.

- Palliative radiotherapy.
- Palliative radiation with 30–35 Gy over 10–15 fractions, has been shown to improve dysphagia in 70% to 90% of patients [64]. ILRT is another effective method to palliate dysphagia. A Dutch study comparing esophageal stents and 12 Gy ILRT showed that there was rapid improvement in dysphagia with stent placement; however, long-term relief was better with ILRT [65]. The onset of dysphagia improvement with radiation is slow and takes around 2 weeks, but is more long-lasting when compared with other modalities.

- Palliative chemotherapy.

- Multiple regimens have been used in advanced esophageal cancer patients with preserved general condition. Dysphagia relief with chemotherapy is modest. Some studies show prolongation of survival with palliative chemotherapy when compared to best supportive care [66]. Trastuzumab, as targeted therapy, along with chemotherapy may be considered in Her-2 positive metastatic gastroesophageal cancer patients.
- In case of tracheoesophageal fistula, if the tracheal lumen is compromised, tracheal/bronchial stent may be placed. A retrospective review looking at airway involvement in esophageal cancers showed that induction chemotherapy followed by radical intent radiation was feasible in 80% of patients and there was modest improvement in survival [67].
- In patients with poor general condition:

    - Nutritional rehabilitation with nasogastric tube placement.
    - Supportive care.

7.10 Management of Recurrent Disease

- Salvage surgery for localized recurrence.
- Locoregional chemoradiotherapy for localized failures postsurgery.
- Palliative treatment or supportive care.

Table 3 Stage-wise management

Stage	Management
Stage 0 esophageal cancer	Endoscopic resection
	Surgery
Early disease—T1 or T2, N0	Surgery alone
T3 or T4, N0 Any T, N+	Chemoradiation followed by surgery
	Chemotherapy followed by surgery
	Definitive chemoradiation
Any T, any N, M1	Palliative radiotherapy
	Palliative chemotherapy
	Endoscopic-placed stents to provide palliation of dysphagia
	Nd:YAG endoluminal tumor destruction or electrocoagulation
Recurrent esophageal cancer	Salvage with either surgery or chemoradiation in localized treatment failures
	Palliative use of any of the standard therapies, including supportive care

Table 3 presents stage-wise management of esophageal cancer.

8 Summary: How We Do It at TMC

As a tertiary referral center, Tata Memorial Centre, Mumbai, registers around 1200–1300 patients with esophageal cancer annually. They are initially evaluated with upper GI endoscopy to confirm diagnosis and PET-CT for staging when radical intent treatment is planned. Nutritional and pulmonary rehabilitation is started simultaneously. Upper- and middle-third tumors undergo bronchoscopic evaluation.

- Upper-third cervical esophageal cancers: Definitive chemoradiation is the treatment of choice.
- Mid- and lower-third esophageal cancers:
  - Early low volume esophageal disease needs additional EUS for accurate staging. A small proportion of the early lesions (select T1a) undergo endoscopic treatment (EMR/ESD), while most of them (T1, T2 N0) are treated with upfront surgery.
  - Locally advanced operable disease needs additional staging laparoscopy for GEJ adenocarcinoma. Neoadjuvant therapy (NACT or NACRT) followed by surgery is the standard of care for operable cancers. Perioperative chemotherapy (FLOT-4 or ECF regimens) for adenocarcinoma and NACT or NACRT for SCC is administered. CECT thorax is used for response assessment post induction therapy. The preferred surgical approach is TTE with standard two field lymphadenectomy. We perform a radical three field lymphadenectomy for patients with supracarinal nodal disease or as part of a randomized trial. For patients with compromised lung function or high-risk comorbid disease, THE is considered a suitable option and GEJ tumors are approached with LTA incision. Minimally invasive approach is employed in around 30% of patients. The preferred conduit is the stomach through the posterior mediastinal route. We prefer a linear stapled anastomosis and insert a nasojejunal tube for feeding in the immediate postoperative period.
  - Locally advanced inoperable disease is treated with definitive chemoradiation.
  - Metastatic disease patients are managed with either palliative radiotherapy or best supportive care for SCC and palliative chemotherapy for adenocarcinoma.

Esophageal cancer continues to carry dismal prognosis in spite of advances in treatment modalities with 5-year survival varying between 5% and 30%. Multidisciplinary team management is the way forward to try and improve survival in esophageal cancer patients.

PET	Positron emission tomography
SEER	Surveillance, epidemiology, and end result
TNM	Tumor-node-metastasis
USG	Ultrasonography

1 Gallbladder Cancer

1.1 Introduction

Gallbladder carcinoma (GBC) is the fifth most common gastrointestinal tract malignancy [1] with considerable geographical and ethnic variation in the incidence. Worldwide the highest incidences of GBC are reported in South American countries like Chile (16–27/100,000), Ecuador, and Bolivia, and in India, south Pakistan, and Central Europe [2]. Worldwide, the age-standardized incidence rate is 2.2 for males and 2.4 for females, while the mortality rate is 1.6 and 1.8, respectively [3]. The lifetime risk of developing GBC is 0.25 for males and 0.26 for females.

GBC has a distinct demographic divide in India with the highest prevalence in the northern states of Uttar Pradesh, Bihar, Orissa, West Bengal, and Assam [4, 5] and is the leading gastrointestinal tract cancer in women residing in north Indian cities [6]. According to Tata memorial hospital registry, it is the fourth most common malignancy in females [7]. The incidence of GBC increases after the age of 45 years and is maximum at the age of 65 years [8].

The overall 5-year survival for GBC is only 20%. Five-year overall survival for various stages is stage I, 62.5%; II, 50.2%; IIIA, 25.7%; IIIB, 22.1%; IVA, 15.7%; IVB, 6.7%.

1.2 Etiology and Risk Factors

1.2.1 Age and Gender

GBC rates increase with increasing age with a median age in the sixth decade of life. Increasing age also corresponds to an increase in mortality [2].

GBC is twice more common in women than men and is correlated with increased parity and a greater number of pregnancies [2, 9]. Marked female predominance is seen especially in northern India, Pakistan, and the American Indian population.

1.2.2 Geography and Ethnicity

There is a wide difference in the geographical pattern for GBC with very high incidence in Asia and South America, with Asia being the high-risk continent [2]. The highest incidence is seen in north Indian and Pakistani women and Korean men. GBC is also common in indigenous populations of Makuchi Indians and American Indians [9, 10]. The incidence is relatively low in most Western and Mediterranean European countries.

1.2.3 Gallstones

There is no direct causal relationship between gallstones and GBC, although 75–98% of all GBC patients have associated cholelithiasis. However, the incidence of GBC gallbladder cancer in a population of patients with gallstones is only 0.3–3% [9]. Gallstones carry a relative risk of 4.9 for GBC [2]. Stones larger than 3 cm and cholesterol gallstones carry an increased risk [9]. Risk factors predicting incidental gallbladder cancer following cholecystectomy include older age, female sex, previous cholecystitis, and the combination of acute cholecystitis without jaundice and jaundice without acute cholecystitis [11, 12].

1.2.4 Chronic Inflammation

Chronic inflammation is a major risk factor for GBC. Gallstones resulting in chronic cholecystitis are a well-recognized risk factor. Chronic inflammation leads to changes in cell proliferation, cell death (apoptosis), DNA mutation rates, DNA methylation, and angiogenesis [9].

1.2.5 Porcelain Gallbladder

Chronic inflammation also results in calcium deposition in the gallbladder wall. Such depositions are more common in elderly women in the sixth decade. Gallbladders with extensive calcifications particularly of stippled or punctate type are considered premalignant with 21% harboring malignancy [13].

1.2.6 Infections

Chronic bacterial infections due to S. typhi/paratyphi and H. bilis are associated with an increased risk for GBC [9].

Malignant transformation is implicated via the degradation of bile constituents and chronic inflammation itself. A chronic carrier state is associated with an increased risk of GBC with an OR of 4.13, and the association is more prominent in patients without gallstones [14, 15].

1.2.7 Primary Sclerosing Cholangitis

Gallbladder lesions are found in 6% of patients with sclerosing cholangitis with >50% of them harboring malignancy. Increased risk is related to chronic inflammation leading to metaplasia-dysplasia-carcinoma sequence. Cholecystectomy is performed even in polyps <1 cm associated with this disease due to the higher risk of GBC [16].

1.2.8 Obesity

Obesity (BMI >30 kg/m^2) clearly predisposes to GBC. The pooled relative risk for GBC for overweight and obesity is 1.1 and 1.58, respectively, and the risk increases by 4% for each 1 kg/m^2 increment in BMI. The risk is higher in obese females (RR of 1.68) than in males [17].

1.2.9 Gallbladder Polyps

Gallbladder polyps have a prevalence of 0.3–9.5% in the general population with 70% of them being pseudopolyps (cholesterol, focal adenomyomas, inflammatory) which do not carry malignant potential. High-risk features in polyps include large polyps (>1 cm; one-quarter being malignant); a solitary polyp; a sessile polyp; polyp growth; associated gallstones; age over 50–60 years and Indian ethnicity. Cholecystectomy is recommended in the presence of these risk factors [18].

1.2.10 Anomalous Pancreaticobiliary Duct Junction (APBDJ)

APBDJ is a congenital anomaly commonly identified in Asian individuals, particularly of Japanese origin. The carcinogenesis is related to the hyperplasia-dysplasia-carcinoma sequence as a result of the reflux of pancreatic juices into the biliary tract and associated chronic inflammation. Biliary tract cancer is detected in 21.6% of adult patients with congenital biliary dilatation and in 42.4% of adult patients without biliary dilatation with GBC being the most common malignancy [19, 20].

1.2.11 Genetics

Family history is a significant risk factor for GBC. Genetic alterations in oncogenes, tumor suppressor genes, and microsatellite instability predispose to GBC. Proposed carcinogenic pathways include 1) gallstone-mediated inflammation 2) K-ras point mutations (as observed in patients with an anomalous junction of the pancreaticobiliary duct) and 3) neoplastic foci in gallbladder polyps [21].

Genome-wide association study from India has identified a strong association between common genetic variants in the ABCB1 and ABCB4 genes and the risk of gallbladder cancer along with phospholipase C epsilon 1(PLCE1) and liver X receptor beta (LXR) interactions [21, 22].

1.3 Clinical Features

The presentation of GBC is generally nonspecific. Most patients present at an advanced stage with anorexia, jaundice, pruritis, and a lump in the right hypochondrium along with poor performance status.

There is also a possibility of detecting GBC on imaging done for unrelated symptoms. "Incidental GBC" is termed when GBC comes as a surprise finding upon histopathological examination of the cholecystectomy specimen, without suspicion on pre-operative imaging or on intra-operative findings.

1.4 Diagnosis and Work-Up

1.4.1 Blood Investigations

Derangement of liver function tests is a sign of advanced disease. Tumor markers—carcino-embryonic antigen (CEA) and carbohydrate antigen (CA 19–9) are uncertain for diagnosis as these are not specific for GBC. A CEA >4 mg/mL and CA 19–9 with a cut-off value of >20 IU/mL have a sensitivity of 50% and 79% and specificity of 93% and 79% respectively [14, 23].

1.4.2 Imaging

Ultrasonography (USG)

Findings that are suspicious of GBC are the presence of asymmetric wall thickening or calcification, and gallbladder mass with loss of a fat plane between the gallbladder and liver. Gallbladder polyps over 1 cm in diameter are highly suspicious. Other useful USG findings are enlarged nodes, infiltration into surrounding organs, liver metastasis, and biliary dilatation, [24]. The sensitivity of USG in the advanced stage is 84.6% and global accuracy is 90.5% [25]. However, for early lesions diagnostic accuracy is less.

Contrast-Enhanced Ultrasonography (CEUS)

Contrast-enhanced ultrasound using microbubbles as a contrast agent has shown promising results to differentiate malignant lesions in the gallbladder. The sensitivity and specificity for differentiating these lesions on CEUS are 0.81 and 0.87 respectively. Features suggestive of malignancy include discontinuity of the gallbladder wall, infiltration to the surrounding tissue during enhancement, tortuous intralesional vessels, and thickened gallbladder wall [26].

Computed Tomography (CT) Scan

Contrast-enhanced CT is the best modality to define the loco-regional extent of disease as well as distant metastasis (Fig. 1). On a CT scan, GBC usually appears as a mass or a focal or diffuse thickening of the gallbladder wall. Tumor mass is usually heterogeneous with non-uniform uptake of contrast. A CT scan helps stage the disease more accurately by depicting invasion into adjacent liver parenchyma or bile duct and metastases to the liver, periportal and retroperitoneal nodes, and peritoneum. The sensitivity of CT is 0.36 to 0.47 for N-staging (PPV: 0.94; NPV: 0.92); 0.65 for hepatic infiltration of <2 cm (PPV: 0.77) and 1.0 for >2 cm (PPV: 1.0) [27].

Magnetic Resonance Imaging (MRI) and Magnetic Resonance Cholangiopancreatography (MRCP)

MRI and MRCP (Fig. 2) are of particular value in patients presenting with obstructive jaundice. They help in detecting accurately the extent of the bile duct and vascular involvement.

Endoscopic Ultrasonography (EUS)

EUS has an overall accuracy of 80% to detect gallbladder anomalies [26]. Other advantages include assessment of depth of invasion, vascular invasion, periportal lymphadenopathy, and allowing FNAC from suspicious areas/lymph nodes.

[18F]-2-Deoxy-D-Glucose (FDG) Positron Emission Tomography (PET)

In patients with GBC, 18-FDG positron emission tomography (PET)-CT detects occult peritoneal, omental, and/or lymph node metastases with a sensitivity of 56% (Fig. 3)

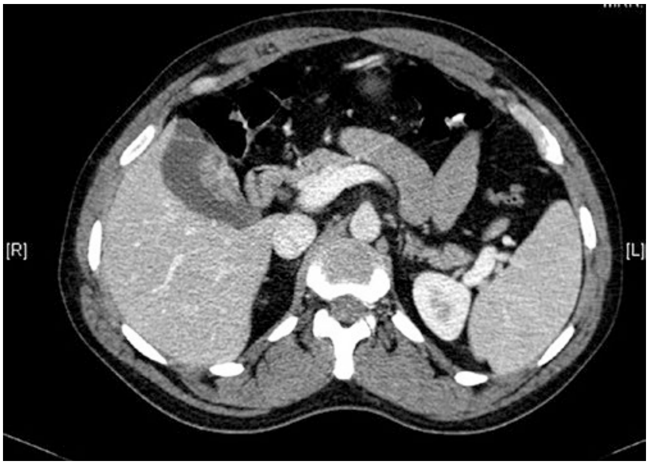

Fig. 1 Early gallbladder cancer

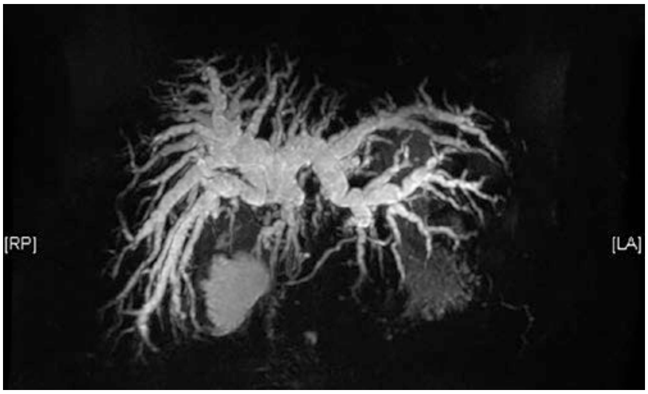

Fig. 2 MRCP showing type I block

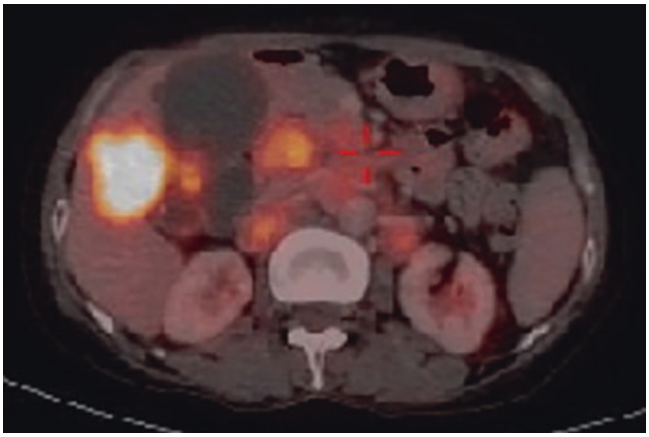

Fig. 3 PET CT showing retroperitoneal nodes

[18]. There is an emerging role of FDG PET scans in incidental GBC with 78% sensitivity and 80% specificity in detecting residual disease [28, 29]. FDG PET CT scans should be done at least 4–6 weeks after any surgical intervention to avoid false positives.

1.4.3 Biopsy and Cytology

A biopsy is not indicated in resectable GBC to avoid seeding of the peritoneum, biopsy tracts, and surgical wounds [30]. Percutaneous FNAC and core needle biopsy should be performed for unresectable or metastatic lesions not considered for upfront surgical resection. Percutaneous biopsy has an accuracy rate of above 90% with a negligible false positive rate. Sensitivity for bile cytology is approximately 75% and is unwarranted in resectable patients.

1.4.4 Staging Laparoscopy

Staging laparoscopy should be done in all patients with resectable advanced GBC or incidental GBC before proceeding to radical surgery to rule out distant and peritoneal metastases. It can prevent a non-therapeutic laparotomy in 38–62% of patients and help in the detection of N2 disease [31]. The yield is highest for patients with T3 disease, poor differentiation, or positive cystic duct margin status [32].

1.5 Staging

Multiple staging systems have been proposed in the past for GBC staging—the American Joint Committee on Cancer (AJCC), the Japanese Biliary Surgical Society system, the Nevin system, and the modified Nevin systems. The AJCC TNM staging (eighth edition) of gallbladder cancer is the standard reporting mechanism [33]. For the eighth edition, the T2 category is separated into T2a (stage IIA) and T2b (stage IIB), based on tumor location on the peritoneal or hepatic side of the gallbladder, respectively. This change is based on a multicenter study demonstrating worse survival for tumors on the hepatic side of the gallbladder [34]. Also, N1 is now defined as one to three metastatic lymph nodes, and N2 as four or more metastatic lymph nodes for better prognostic stratification [35].

1.5.1 Pathological Evaluation of Routine Cholecystectomy Specimens

A step-wise sampling protocol should be followed to identify early dysplastic lesions [36, 37]. In areas of high GBC prevalence even with normal gross examination, a minimum of three random areas and the cystic duct margin should be submitted for microscopic assessment. A thorough sampling is also necessary in the presence of high-risk features like a choledochal cyst, APBDJ, sclerosing cholangitis, and hyalinizing cholecystitis/porcelain gallbladder.

1.5.2 Treatment

Surgery

Surgery is the definitive treatment for non-metastatic GBC (Fig. 4). The standard surgery for GBC includes en-bloc removal of the gallbladder with wedge excision of the liver (2.5–3 cm liver wedge/segment IV b and V) or anatomical segment IVB/V excision along with radical periportal lymphadenectomy and a frozen section for negative cystic duct margin.

The Extent of Liver Resection

The goal is to obtain R0 resection with negative margins. The size of the wedge liver resection depends on the depth of the tumor infiltration and bile duct involvement, ranging from limited segment IVB and V wedge resections to formal anatomic resections [38].

There is no survival advantage of major hepatectomy or formal segment IVb/V resection compared with non-anatomic R0 resection of the liver wedge/gallbladder bed [39–41].

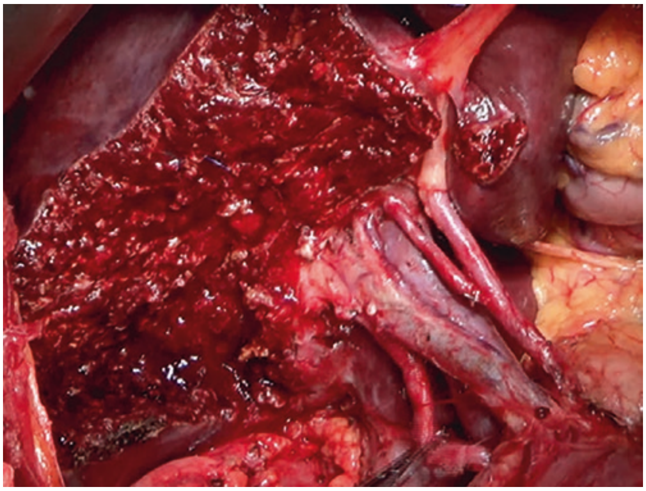

Fig. 4 Complete periportal lymphadenectomy with liver wedge resection

Lymph Node Dissection

Lymph node involvement varies by T-stage, approximating 12%, 31%, and 45% in patients with T1b, T2, and T3 tumors, respectively [40]. The presence of N1 nodal disease is not considered an absolute contraindication to surgical resection. Removal of at least six lymph nodes is recommended for accurate staging [42].

Inter-aortocaval nodal (Station 16) sampling forms the first step of lymphadenectomy. The presence of a positive station 16 lymph node indicates non-regional lymph nodal metastasis [43]. The highest peri-pancreatic lymph node is the transition between the N1 and N2 fields with a good prognostic value. A standard portal lymphadenectomy for GBC includes nodes in the porta hepatis, gastrohepatic ligament, and retroduodenal space (Station 8,12,13).

Bile Duct Resection

Routine bile duct resection has no role in GBC surgery and is not associated with higher lymph node yield [44]. Radical cholecystectomy with extrahepatic bile duct resection should be performed for patients with positive cystic duct margin or if there is a need to achieve nodal clearance for bulky nodal disease involving hepatoduodenal ligament, with GBC involving the neck and cystic duct with direct infiltration of bile duct [45]. Routine bile duct resection should be avoided to prevent additional morbidity.

Role of Multi-Visceral Resection—Major Hepatectomy and Hepatopancreaticoduodenectomy

In the absence of outcome data, associated morbidities, and inherent aggressive tumor biology, these resections are not routinely performed and are not recommended. However smaller series have reported good outcomes in carefully selected patients [46].

A major hepatectomy may be considered in the absence of hepatic arterial involvement or liver metastases [47]. Hepatopancreaticoduodenectomy is associated with a postoperative morbidity rate of 78.9% and a mortality rate of 10.3% with postoperative hepatic failure being the most common reason for mortality [48]. However, it can provide a rare chance of long-term survival in patients in whom R0 curative resection is feasible.

Role of Minimal Invasive Surgery

Radical cholecystectomy with a minimally invasive approach is rarely reported due to the perceived risk of gallbladder perforation and peritoneal dissemination [49, 50]. Two systematic reviews for a minimally invasive approach concluded that it cannot be considered as a dogmatic contraindication for GBC and when performed at a highly specialized center is safe and feasible [51].

The da Vinci robotic surgical system (dVSS) with its improved dexterity, surgeon-controlled camera, and 3D vision has resolved many technical problems associated with a conventional laparoscopic approach and has shown equivalent perioperative and short-term oncological results as compared to open radical cholecystectomy [52, 53].

Early GBC (pTis and pT1a)

Early GBC is suspected preoperatively in only 30–40% on imaging with most of them discovered incidentally on histopathological examination of cholecystectomy specimens performed for other reasons.

The optimum treatment for pTis and pT1a GBC is simple cholecystectomy with a negative cystic duct margin with a cure rate of 85–100% [54]. However, the presence of perineural or vascular invasion on histopathology or bile spill during cholecystectomy may adversely affect long-term survival [55].

pT1b GBC

The incidence of nodal metastases with T1b disease is 3.8–25% [56]. Radical cholecystectomy for T1b disease includes cholecystectomy with en-bloc hepatic bed resection (2–3 cm wedge resection or segment IVb + V) and peri-portal lymphadenectomy with or without bile duct excision for negative margin [57].

pT2 GBC

T2 disease has lymph node metastasis in 20–62%, mainly to hepatoduodenal ligament and location of the tumor on the hepatic side, i.e., pT2b carries poor prognosis due to higher rates of nodal positivity and vascular invasion [58]. In these patients, radical cholecystectomy is the treatment of choice. SEER database has shown a survival benefit with extended surgical resection and lymph node dissection with pT2 GBC [59]. In a study by Matsumoto et al., 3 years of survival of

Stage II GBC treated with simple vs. radical cholecystectomy was 57% vs. 100% [60].

Incidental GBC

The incidence of incidental GBC is 0.35–2% [61]. Incidental GBC gallbladder cancer has a better prognosis compared to non-incidental disease if managed appropriately with R0 resection. The incidence of residual disease is as high as 37.5% in T1 tumors, 56.7% in T2 tumors, and 77.3% in T3 tumors [62].

On suspicion of GBC during laparoscopic surgery, the procedure should be aborted and the patient referred to a specialized hepatobiliary center. A review of pre-cholecystectomy imaging and a discussion with referring surgeon regarding intra-operative findings should be done. Both CT scans and MRIs provide critical information in re-staging the patients. There is now an increasing role of PET scans in restaging disease in incidental GBC. The management of incidental GBC is guided by the TNM stage. Radical re-resection or revision surgery is advocated in patients with pT1b and above GBC. Delaying resection has no effect on the outcome of the disease. There is no significant impact on the time interval between cholecystectomy and radical re-resection [63]. Revision surgery should be performed whenever feasible.

Port Site Resection

Port site resection was advocated in the past to reduce the local wound recurrence due to the possibility of tumor contamination at the time of laparoscopic cholecystectomy. Recent evidence suggests port site metastases as a harbinger of generalized peritoneal recurrence that would not be prevented with resection of these sites. Port site resection is not associated with improved overall survival or recurrence-free survival [64] and is no longer considered as part of standard surgery for GBC.

Locally Advanced GBC (T3, T4, and Node-Positive) and Role of Neoadjuvant Treatment

T3 disease has a higher incidence of residual disease-36% and metastatic nodes-46%. Management includes radical resection of the gallbladder fossa with portal lymphadenectomy and a negative cystic duct margin. In the case of T4 disease, the role of extensive vascular reconstructions in the treatment of gallbladder cancer has not been shown to provide a survival benefit. All such patients can be termed as 'high risk' GBC and may be offered neoadjuvant treatment.

Role of Neoadjuvant Chemotherapy (NACT)

The neoadjuvant approach to GBC has emerged as a bridge to possible surgery as well as an assessment of disease biology based on the assessment of response to NACT or CRT. Engineer et al.'s study of 28 patients with T3/T4 disease with fixed portal nodes used CRT with gemcitabine and achieved an R0 resection rate of 56% and mOS of 20 months [65].

Considering the systemic nature of GBC as well as a predominantly distant recurrence pattern as opposed to locoregional recurrences, the use of NACT with lesser morbidity is likely to be the treatment of choice. The use of a gemcitabine-platinum combination (either cisplatin or oxaliplatin), based on the regimen's efficacy has been explored in two retrospective studies from the Tata Memorial Hospital and MSKCC, respectively. R0 resection rates were 46% and 14%, respectively, though mOS was similar in both cohorts (13.4 months and 14 months respectively) [66, 67]. Chaudhari et al. in their study evaluating the role of NACT, defined the criteria for high-risk disease (TMH criteria- based on clinic-radiological parameters). These criteria can be used in the future to select patients for NACT in GBC [68].

A randomized study comparing chemotherapy alone with CRT in locally advanced GBC satisfying pre-defined criteria is currently recruiting in Tata Memorial Hospital and may provide answers post-completion [69].

1.6 Adjuvant Therapy

Studies on adjuvant treatment in GBC are retrospective in nature. External beam radiotherapy (EBRT), intra-operative radiotherapy (IORT), and brachytherapy with or without chemotherapy have been used in the past for adjuvant treatment of GBC [69–75].

Currently, adjuvant therapy is recommended in all patients with stage II to IVA GBC patients who have undergone radical cholecystectomy. Patients who have tumor confined to lamina propria that is diagnosed incidentally do not need adjuvant treatment as their survival approaches 100% with simple cholecystectomy alone [76].

1.6.1 Adjuvant Chemotherapy

A phase III RCT from Japan by Takada et al. [77] evaluated the role of adjuvant chemotherapy in pancreatobiliary cancers. The 5-year OS and disease-free survival rate in GBC patients was significantly better in the chemotherapy group (26.0%, 20.3%) compared with the control group (14.4%, 11.6%) ($p = 0.0367$, $p = 0.0210$). However, statistically significant survival benefit was observed in patients who underwent non-curative resection (8.9% vs. 0%; $p = 0.0226$) but not in patients with completely resected GBC.

The lack of adequate randomized phase III data suggesting a definitive benefit to adjuvant therapy has hampered the uptake of this modality in biliary tract cancers (BTC) till recently. However, multiple retrospective studies, single-arm studies, and meta-analyses have suggested that improved outcomes post resected BTC have been a combination of standardized surgical techniques as well as adjuvant therapy.

The majority of available evidence for the role of adjuvant therapy in resected BTC has been crystallized in three well-conducted meta-analyses [78–80]. These studies primarily comprise retrospective and single-institution studies (which is indicative of the lack of randomized data in these tumors) as well as a mix of CC and GBC, the following suggestions for adjuvant therapy are to be considered:

1. There appears to be no major difference in terms of outcomes between CC and GBC when adjuvant therapy is received.
2. The strongest evidence for the benefit of adjuvant therapy is in the presence of lymph node-positive disease and R+ resections.
3. Adjuvant chemotherapy and adjuvant CRT are potentially superior to adjuvant radiotherapy alone, though there is no available data or consensus as to the primacy of chemotherapy over CRT or vice-versa.
4. There is no available data to suggest the adjuvant chemotherapy regimen of choice. Guidelines suggest the use of regimens that are effective in advanced unresectable BTC (e.g., gemcitabine-cisplatin, gemcitabine-oxaliplatin).

The PRODIGE 12-ACCORD 18 (UNICANCER GI) study and the BILCAP studies are two randomized studies in the current era which have further defined the role of adjuvant chemotherapy in resected BTC [81, 82]. While the PRODIGE-ACCORD trial used the gemcitabine-oxaliplatin regimen versus observation as an adjuvant, BILCAP randomized patients to single-agent capecitabine or observation. The PRODIGE-ACCORD trial did not reach its primary endpoint of superior recurrence-free survival (RFS) [30.4 months for gemcitabine-oxaliplatin vs. 22 months for observation, p = 0.31; HR - 0.83 (95% CI: 0.58–1.19], the BILCAP study reached its primary endpoint of statistically superior mOS (53 months for capecitabine vs. 36 months for observation, HR 0.75 [95%CI 0.58, 0.97; p = 0.028]) on per-protocol analysis. While the BILCAP study does suggest that single-agent capecitabine may be considered as one of the current standards of care, certain caveats do exist. The study considered BTC as a whole, whereas it is well known that GBC and CC have different molecular characteristics and behavior. Secondly, the lack of patients in these studies from high-endemic regions of BTC (Chile, India, Thailand, etc.) may hamper the generalization of this data across regions.

1.6.2 Adjuvant Chemoradiotherapy (CTRT)

The evidence for the use of adjuvant (chemo) radiation for patients with resected gallbladder cancer is supported by Surveillance, Epidemiology and End Result (SEER) database that included 1137 patients. While the SEER database analysis support use of adjuvant chemoradiation in stage >pT2, pN+ patients the absolute benefit in an individual patient may be estimated using proposed nomograms [83]. A dose of 45 Gy in 25 fractions over 5 weeks may be acceptable and has been shown to improve outcomes in patients with GBC. A boost of 5.4 Gy may be considered in an R1 resection. The limiting feature of local irradiation is the tolerance of surrounding critical structures, including the liver, kidneys, pancreas, lesser curvature of the stomach, and small bowel.

Another analysis of the National Cancer Database that included 5029 patients reported improved survival in all patient categories apart from T1N0 and is also supported by multi-institutional analysis [84, 85]. However, despite this evidence, the utilization of adjuvant chemotherapy or chemoradiation is low, and prospective randomized trials should be done to confirm the efficacy of adjuvant chemoradiation over adjuvant chemotherapy in high-risk resected gallbladder cancer.

1.7 Management of Unresectable/ Metastatic GBC

The current standard of care for patients with unresectable BTC with good performance status and adequate organ function is palliative chemotherapy with concurrent early palliative care. The benefit of palliative chemotherapy over best supportive care (in terms of quality of life and prolongation of life) was proven with a small randomized study as early as 1996 [86]. Since then, various chemotherapeutic regimens, predominantly combining 5-fluorouracil, capecitabine, gemcitabine, and either of the platinum have been used in various combinations to improve survival. The ABC-02 and BT-22 studies established gemcitabine-cisplatin as the current standard of care when compared to single-agent gemcitabine alone [87, 88]. The gemcitabine—oxaliplatin combination is also commonly used with a study from AIIMS having shown its superiority of 5—fluorouracil and best supportive care [89]. Available evidence suggests that both platinum-based doublets have similar efficacy and outcomes. The combination of gemcitabine and S1 (an oral drug combining tegafur, gimeracil, and oteracil potassium) has also shown non-inferiority to gemcitabine-cisplatin as per the results of the Japanese JCOG1113- FUGA-BT study [90].

The use of monoclonal antibodies (e.g., bevacizumab) and anti-EGFR tyrosine—kinase inhibitors (e.g., cetuximab, Panitumumab, etc.) in unresectable BTC has not shown significant benefit and the use of such drugs is not currently recommended outside the setting of a clinical trial.

The role of chemotherapy as opposed to active symptom control post progression on first-line chemotherapy is an unanswered question, though studies like the ABC-06 may provide answers in the future.

1.8 Palliative Care

Patients with advanced disease often experience severe upper abdominal pain which should be treated in a stepwise manner with escalating doses of non-opioid and opioid drugs and celiac plexus block under imaging in unrelenting cases.

Biliary obstruction leading to jaundice and pruritus should be relieved by biliary stenting (preferably metallic). Stents may be placed by percutaneous or endoscopic routes. Segment III biliary bypass done to relieve malignant jaundice is now obsolete with advanced non-operative techniques of drainage. However, it may still be helpful for a select few patients in a resource-constraint environment.

Few patients experience gastric outlet obstruction due to direct tumor infiltration or compression from surrounding lymph nodes and they may need a gastrojejunostomy.

The aim of all the above interventions is to improve the quality of life in patients with otherwise limited treatment options and poor prognoses.

2 Cholangiocarcinoma

2.1 Introduction

The term cholangiocarcinomas (CCAs) refers to all the tumors arising from the biliary ductal system. As per the anatomical location, they are divided into intrahepatic, perihilar, and distal. Intrahepatic CCAs present as liver masses while Perihilar CCA also known as Klatskin's tumor involves the confluence of the left and right ducts and usually both intra- and extrahepatic ducts [91]. Distal CCAs involve the common and/or proper hepatic duct without extension to the confluence and usually involve the intrapancreatic portion of the bile duct. The perihilar CCAs are the most common subtype (67%), followed by distal (27%), and then intrahepatic (6%). Most intrahepatic CCAs are mass forming, while perihilar have periductal infiltrating growths, and distal CCAs have intraductal growths. The majority of CCAs are adenocarcinomas and are subdivided into three histologic subtypes: sclerosing, nodular, and papillary with papillary carrying the best prognosis. Ninety-five percent of perihilar CCAs are sclerosing variants with very low resectability rates.

CCAs are slow-growing tumors with infiltration along the wall of ducts and extending to surrounding structures. Management is difficult due to associated biliary obstruction and subsequent risk of cholangitis and liver failure. One and two-year survival following diagnosis are 25% and 13%, respectively, with few reported long-term survivors. A 5-year survival rate of 25–30% has been reported in patients with R0 resection [92].

2.2 Etiology and Risk Factors

The incidence of CCAs increases with age, and the majority of patients are 65 years and older. The peak incidence is in the eighth decade of life. Men are affected more commonly than women. Risk factors for CCAs are associated with chronic inflammation of the biliary duct epithelium.

2.2.1 Primary Sclerosing Cholangitis

Patients with primary sclerosing cholangitis have a lifetime risk of about 10% and 1.5% per year from the onset of the disease. They usually present with multifocal disease due to the involvement of several ducts.

2.2.2 Choledochal Cysts

Congenital choledochal cysts increase the risk of cancer due to associated inflammation and bacterial infection. Approximately, 15–20% of patients with unexcised cysts or cysts treated with biliary bypass develop CCA. Complete surgical removal in childhood reduces the chances of malignancy in later life.

2.2.3 Liver Fluke Infestation

biliary parasites such as Opisthorchis viverrini and Clonorchis sinensis contribute to increased risk, especially in Southeast Asia, where incidence can reach 87 per 100,000.

2.2.4 Others

Chronic ulcerative colitis, liver infection, exposure to carcinogens (including thorium dioxide, asbestos, radon, dioxin, nitrosamines, and cigarette smoke), chronic intrahepatic stones, and Hepatitis C are associated with increased risk of CCA [93].

2.3 Clinical Features

Most patients have non-specific symptoms and therefore difficult to diagnose. Painless jaundice is the commonest complaint of patients with CCA and is seen in about 70–90% of patients, followed by pruritis (66%), abdominal pain, weight loss (30–50%), and fever in about 20% [92, 94]. Jaundice occurs early with distal and hilar CCAs, but late with intrahepatic CCAs [95] where it is a marker of advanced disease.

2.4 Diagnosis and Work-Up

The differential diagnosis of cholangiocarcinoma includes benign strictures (post-operative bile duct injury, choledocholithiasis, primary sclerosing cholangitis, recurrent pyogenic cholangitis, ischaemic cholangitis, Mirrizi's syndrome and other malignancy like diffuse intrahepatic metastasis or metastatic hilar lymph node. Therefore, a good knowledge of these mimicking diseases along with clinical and imaging findings is necessary for diagnosis of cholangiocarcinoma. In patients with early resectable disease histological diagnosis should not be mandatory before surgery [93].

2.5 Imaging

USG: Ultrasonography of the abdomen is the first investigation ordered in a patient presenting with obstructive jaundice. Ultrasound may demonstrate biliary duct dilatation and larger hilar lesions. Small lesions and distal CCAs cholangiocarcinomas are difficult to visualize.

Magnetic resonance imaging (MRI)/magnetic resonance cholangiography (MRCP) should be performed to define the appearance and location of the bile duct stricture and determine the type of block. Irregular strictures at the confluence are consistent with the diagnosis of hilar cholangiocarcinoma.

Helical multi-detector computed tomography (CT) is also accurate in diagnosing the level of biliary obstruction. It may demonstrate ductal dilatation and mass lesions. The CT scan will usually demonstrate thickening of the bile duct at the level of obstruction with dilated ducts proximal to it [96]. Three-dimensional helical CT cholangiography can also help in assessing vascular invasion and nodal involvement preoperatively [97].

Positron emission tomography (PET)—computerized tomography (CT) could lead to a change in surgical management in 25% of cases with the detection of unsuspected distant metastases [98]. It has limited sensitivity for infiltrating lesions as the density of metabolically active cells in the setting of intense fibrosis is less. Moreover, inflammation due to benign causes may give rise to false positive results.

Cholangioscopy either perorally or by percutaneous approach provides direct visualization of biliary epithelium, a more targeted biopsy compared with fluoroscopy-guided forceps biopsy, and thus may facilitate tissue acquisition for diagnosing suspected malignant biliary strictures. It has a high technical and procedural success rate for the visualization of biliary lesions improving the diagnosis of biliary strictures. Cholangioscopy may be considered after prior negative conventional sampling.

2.6 Biopsy and Cytology

Due to low yield and sensitivity, it may be reasonable to proceed to surgery without tissue diagnosis. Patients with symptomatic jaundice should undergo biliary drainage preoperatively to allow the liver to recover before resection. For distal strictures or in palliative cases ERCP should be performed which helps in visualization of the proximal duct, stenting of the obstruction, and also to obtain brush cytology. Perihilar strictures should be managed with a percutaneous transhepatic cholangiographic approach.

Endoscopic ultrasound-directed fine-needle aspiration has an accuracy of 91%, sensitivity of 89%, and specificity of 100% in the diagnosis of patients with perihilar CCA [99]. These tumors are often hypocellular and difficult to diagnose by cytology or biopsy.

2.7 Staging

The tumor-node-metastasis (TNM) system eighth edition 2017 devised by the American Joint Committee on Cancer is used for staging cholangiocarcinoma [100]. Bismuth developed a classification system for surgeons to define the extent of biliary resection, however, it lacks the information on the presence of vascular involvement, and parenchymal atrophy (Fig. 5) which can be accessed at https://www.nejm.org/doi/full/10.1056/nejm199910283411807

Type I	Tumor involves the common hepatic duct
Type II	Tumor involves the bifurcation of the common hepatic duct
Type IIIa	Tumor involves the right hepatic duct
Type IIIb	Tumor involves the left hepatic duct
Type IV	Tumor involves both the right and left hepatic ducts

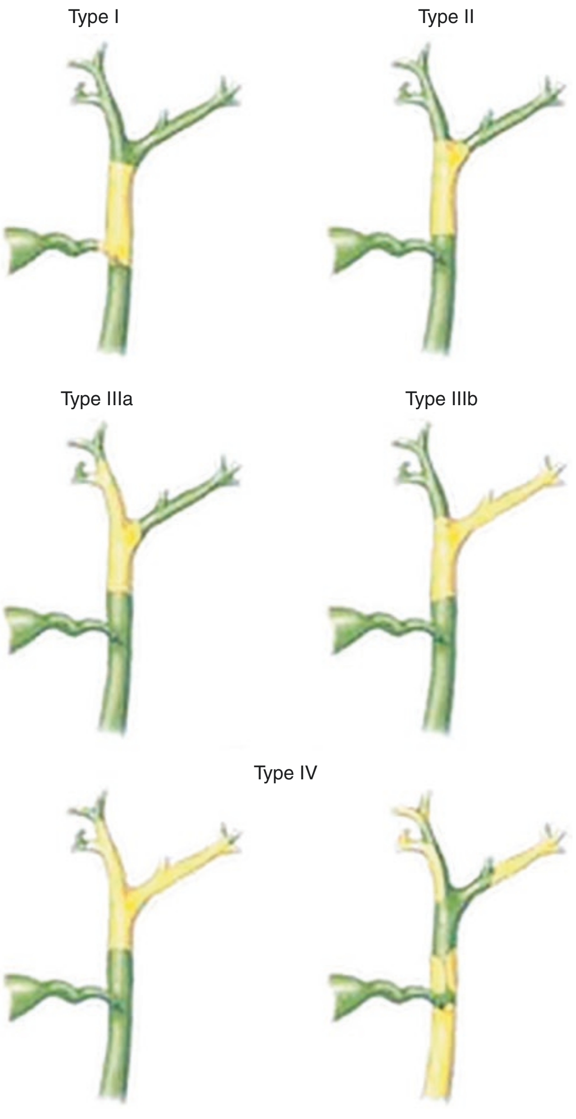

Fig. 5 Bismuth classification of perihilar CCA

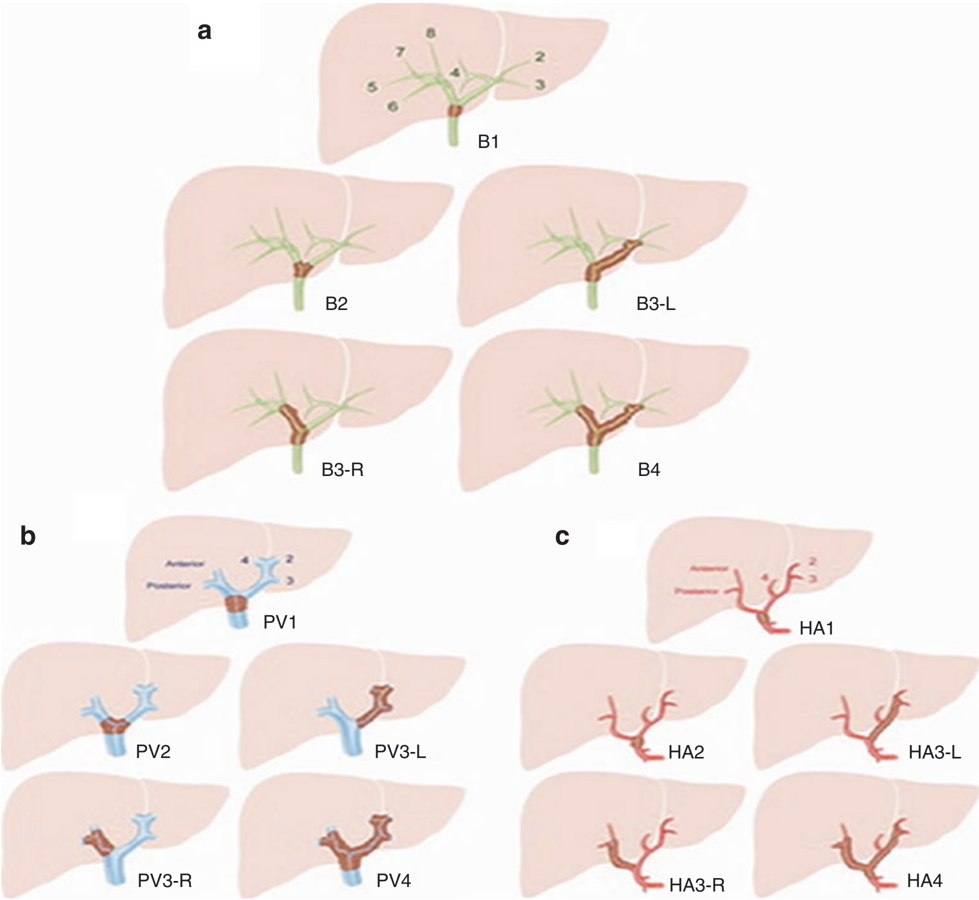
Fig. 6 New staging system



A new staging system incorporating tumor size, extent of disease in the biliary system, involvement of hepatic artery and portal vein, nodal involvement, distant metastases, and the volume of remnant liver after resection has been reported (Fig. 6) [101].

2.8 Treatment

2.8.1 Pre-Operative Management

Pre-Operative Biliary Drainage

Even though the advantage of pre-operative biliary drainage (BD) is not demonstrated, there is a trend to consider BD in three situations: (1) when future liver remnant is less than 40% of the total liver volume and if portal vein embolization is considered; (2) cholangitis resistant to antibiotics; (3) renal failure or malnutrition due to hypoalbuminemia. The disadvantages are the subsequent bacterial colonization of bile and cholangitis, which may delay surgery [102]. The stent itself may lead to a dense fibrous reaction that can be difficult to differentiate from the tumor.

2.9 Surgery

Complete surgical resection is the only therapy to afford a chance of cure (Fig. 7). Unfortunately, only 10% of patients present with early-stage disease and are candidates for curative resection.

2.9.1 Intrahepatic CCA

The goal of resection is to remove all liver parenchyma at risk based on the proximal extent of the tumor. Usually, this requires partial hepatectomy or lobectomy for intrahepatic tumors. The presence of lesions in the contralateral lobe and distant metastases portends a poor prognosis and is considered a contraindication to resection.

2.9.2 Hilar CCA

Resection of the involved intra- and extra-hepatic bile ducts, as well as the associated liver segments and caudate lobe along with complete peri-portal lymphadenectomy, is the standard of care. Curative resection with histologically negative margins (R0) is associated with a median survival of 27 months to 58 months and 5-year survival rate of 27–45%, as

compared to 12 months to 21 months and 0–23% in the presence of histologically positive margins (R1) [104, 105].

Criteria for Unresectability of Hilar CCA [106]

The criteria that determine unresectability in hilar CCA are a requirement of biliary reconstruction options and adequate future liver remnant. Any of the following criteria can categorize hilar cholangiocarcinoma as unresectable:

- Bilateral segmental ductal extension (type IV involvement).
- Unilateral atrophy with either contralateral segmental ductal or vascular inflow involvement.
- Unilateral segmental ductal extension with contralateral vascular inflow involvement.

Staging laparoscopy has a yield of 27% to detect peritoneal or liver metastases and avoids unnecessary laparotomy [106]. Staging laparoscopy should be performed in all patients before exploratory laparotomy.

In patients eligible for resection, a choice between a right-sided and a left-sided hepatectomy is made depending on the involvement of second-order bile ducts or lobar atrophy. Right-sided resections are performed more frequently compared to left-sided ones with no difference in R0 resection rates, survival, or portal vein reconstructions. Hepatic artery reconstructions are needed more frequently with left hemihepatectomy due to the close anatomic relation of the right hepatic artery to the bile duct bifurcation.

Studies demonstrate that 46% of perihilar CCA microscopically involve the caudate lobe with a five-fold increase in R1 resection rates when caudate lobectomy is omitted. Therefore, caudate lobe excision should always be performed for perihilar cholangiocarcinoma.

Recently parenchymal-sparing approaches such as “Taj Mahal resection”, “combined caudate lobe and high hilar resection (CCHR)” or “dumbbell form resection (DFR)” are being propagated which involve anatomic or nonanatomic resection of segments I and IV and V with en-bloc extrahepatic bile duct resection.

Postoperative complications include wound infection, liver or subphrenic abscess, cholangitis, pulmonary embolus, gastrointestinal hemorrhage, and small bowel obstruction with mortality rates up to 5–10%.

2.9.3 Liver Transplantation

If a positive margin or inadequate future liver remnant is anticipated, a liver transplant should be considered for nonmetastatic hilar cholangiocarcinoma. The Mayo Clinic protocol can be used utilized using neoadjuvant chemoradiation followed by liver transplant [107].

In a multicenter study from the United States evaluating the role of neoadjuvant chemoradiotherapy and transplant, post-transplant 5-year recurrence-free survival was 65% [108].

However, very few patients meet the criteria for this option. The inclusion criteria include unresectable perihilar cholangiocarcinoma 3 cm or less in radial diameter without intrahepatic or extrahepatic metastases. Patients with perihilar cholangiocarcinoma developing in a background of primary sclerosing cholangitis should be treated, when possible, with liver transplantation.

2.10 Adjuvant Therapy

2.10.1 Radiotherapy

In general, postoperative adjuvant radiotherapy reduces the risk of local recurrence and potentially improves survival. A recent meta-analysis of 44 studies including patients undergoing resection for extrahepatic biliary tract carcinomas found that adjuvant radiotherapy was associated with improved overall survival with a hazard ratio (HR) of 0.62 (95% CI 0.48–0.78, $P = <0.001$) after exclusion of studies with ampullary or gallbladder cancer patients [109]. Low rates of radiation-induced toxicity were noted.

Postoperative adjuvant radiotherapy for biliary tract cancer can be administered either by external-beam radiotherapy (EBRT), brachytherapy, intraoperative radiotherapy (IORT), or a combination of radiotherapy modalities.

2.10.2 Combined Chemo-Radiotherapy

Preliminary results from the Southwest Oncology Group (SWOG)-S0809 phase II study of adjuvant capecitabine plus gemcitabine followed by concurrent capecitabine with radiotherapy in radically resected CCA and GBC were presented at the 2014 ASCO meeting [110]. Eligibility criteria included R0 resection for patients included extra-hepatic cholangiocarcinoma or gallbladder cancer, lymph node-positive disease, and R1 resections. Of 79 patients, 62% were extrahepatic CCA, and 86% completed planned therapy. Grade 3 or 4 toxicity rate was 64% overall (particularly neutropenia and hand-foot syndrome). For the patients with extrahepatic cholangiocarcinoma ($n = 49$) the 2-year overall survival, 2-year disease-free survival, and local relapse was 66% (95% CI 50–78), 51% (95% CI 36–65), and 11% (95% CI 2–21), respectively.

In summary, despite the lack of conclusive evidence in support of adjuvant therapy, chemoradiotherapy is recommended for patients who have had a resection with curative intent, especially when the tumor has invaded into or through the muscularis layer, the margins of resection are involved, or regional lymph nodes are involved.

European Society of Medical Oncology (ESMO) practice guidelines recommend adjuvant (5-FU-based) chemotherapy for patients with GBC and the possible use of chemoradiotherapy for cholangiocarcinoma where local relapse rates were estimated to reach 52% [111].

2.10.3 Chemotherapy

The most relevant studies in the adjuvant setting are ESPAC-3, BILCAP, and a meta-analysis. European Study Group for Pancreatic Cancer-3 trial [112], the largest randomized trial was conducted in patients with resected periampullary adenocarcinomas. Four hundred and twenty-eight patients with periampullary malignancies (96 bile ducts) were randomly assigned to one of three arms: observation, 6 months of leucovorin-modulated FU, or single-agent gemcitabine. The use of adjuvant treatment was associated with a statistically non-significant survival advantage (median 43 months vs. 35 months, HR 0.86, 95%CI: 0.66–1.11). On multivariate analysis, correcting for prognosis factors, survival benefit for chemotherapy was seen specifically for gemcitabine, and with a better safety profile [112].

BILCAP is a multi-center prospective, randomized phase III trial trying to examine the role of adjuvant chemotherapy with an oral fluoropyrimidine (capecitabine) in patients following potentially curative surgical resection of a biliary tract cancer.

The meta-analysis including 6712 patients has shown that the improvement in 5-year survival with any adjuvant therapy was not statistically significant [pooled odds ratio (OR) = 0.74, 95%CI: 0.55–1.01] compared with surgery alone. However, the survival benefit from adjuvant therapy was statistically significant when the data from the two large registry series (*n* = 1233 patients) were excluded (OR = 0.53, 95%CI: 0.39–0.72). There is a statistically significant overall survival advantage for adjuvant therapy in node-positive disease (OR = 0.49, 95%CI: 0.30–0.80) and margin-positive disease (OR = 0.36, 95%CI: 0.19–0.68) [113].

Please refer to the GBC section for adjuvant chemotherapy.

2.11 Advanced Disease

2.11.1 Radiotherapy

Conventionally fractionated radiotherapy with or without concomitant chemotherapy is considered the standard treatment option for inoperable cholangiocarcinoma. One-year actuarial loco-regional control rates on the order of 60%, were observed at M.D. Andersen [114], and extending up to 75%, at the University of Michigan [115]. The corresponding median overall survival rates in these series were 10 and 13 months, respectively.

2.11.2 SBRT in Unresectable Cholangiocarcinoma

Improved local control and survival rates have been observed with higher radiotherapy doses suggesting dose escalation like SBRT as a promising therapeutic approach in the treatment of unresectable bile duct cancer [116].

2.11.3 Chemotherapy

In patients with advanced biliary tract cancer, the survival benefit of chemotherapy over best supportive care alone was suggested in a trial that randomly assigned 90 patients with advanced pancreatic or biliary cancer (37 with bile duct cancer) to 5-FU-based systemic chemotherapy with leucovorin and etoposide versus best supportive care alone (median survival 6 vs. 2.5 months respectively) [86].

The superiority of the combination gemcitabine-cisplatin regimen is shown in the recently published ABC Trial. A combination of gemcitabine and cisplatin improved overall survival and progression-free survival by 30% more than gemcitabine alone. Based on these results, the combination of gemcitabine plus cisplatin is considered the standard of care as first-line chemotherapy for biliary tract cancer treatment [117].

2.12 Palliative Measures

The goal of palliation for bile duct tumors is drainage of the biliary system to avoid jaundice. In many cases, patients will die of liver failure as a direct result of inadequate biliary drainage. Drainage of the bile ducts can be performed using ERCP-placed stents, or PTC-placed stents. Hilar CCAs are best palliated using PTC-placed stents. A small, multicentered randomized controlled trial was performed comparing PTC stents alone with PTC stents plus photodynamic therapy (39 patients total) [118]. Patients receiving photodynamic therapy survived 493 days compared with 98 days for those treated with stenting alone. This suggests a role for photodynamic therapy in these patients. Distal bile duct tumors can be successfully palliated with an ERCP-placed stent.

1 Introduction

Primary cancer of the liver includes hepatocellular carcinoma (HCC), cholangiocarcinoma, hepatoblastoma, sarcomas, hemangioendothelioma and primary lymphomas. HCC accounts for more than 90% of liver cancer, and the main risk factor for its development is liver cirrhosis of any etiology. Clinical presentation is variable, and patients may remain asymptomatic for a long time, presenting with symptoms only when the disease is advanced. When diagnosed at an early stage, it usually incidental or when patients with cirrhosis are on a surveillance program. Imaging is the cornerstone in diagnosis, management and follow-up of these patients.

The prognosis of advanced untreated HCC is dismal with a median survival of 8 months [1]. Prognosis in general depends on whether curative treatment can be given, which is in turn dependent on the tumor burden, liver function and the patient's performance status. Curative treatment in the form of resection, liver transplantation or ablation is associated with a 5-year survival of 40–70%.

HCC will be dealt with here and biliary cancers in a separate chapter.

2 Epidemiology and Etiology

2.1 Epidemiology

HCC is largely a problem of the developing world where majority of the new cases occur. It is the fifth most common cancer in men and the ninth in women but the disparity in rates between the sexes is not well understood. Globally, the distribution of HCC varies by region, sex and etiology. The regions with the highest age-adjusted incidence rates are Eastern and South-Eastern Asia and sub-Saharan Africa. Intermediate rates occur in Southern Europe and Northern America and the lowest rates are in Northern Europe and South-Central Asia [2].

In India, information on HCC epidemiology is unreliable. Based on cancer registries in five Indian urban populations (Mumbai, Bangalore, Chennai, Delhi and Bhopal), liver cancer ranks as the fifth most frequent cancer for both sexes [3]. However, the cancer registries in India probably do not provide accurate estimates of HCC prevalence due to the heterogeneous nature of information sources. Age-adjusted incidence rate of HCC in India for males ranges from 0.7 to 7.5 and for females from 0.2 to 2.2/100000 per year and the male-to-female ratio for HCC in India is 4:1 [4].

2.2 Etiology

Chronic injury and inflammation seem to be the pathological processes leading to HCC development regardless of etiology and liver cirrhosis is the underlying pathology in the majority of HCCs. The cell death in liver cirrhosis leads to a chronic stimulus for cell division and the formation of regenerative noduli. This in turn leads to DNA changes, dysplasia and subsequently malignant transformation. The etiology can be viral, toxic or metabolic.

1. Chronic hepatitis B (HBV) and C (HCV) virus infection account for more than 80% of HCC cases. Both HBV and HCV infected individuals run a significantly greater risk of developing HCC as compared to a noninfected population. This risk is increased in infected individuals when other risk factors coexist including male sex, older age, coinfection with the other hepatitis virus or human immunodeficiency virus (HIV), presence of diabetes mellitus, obesity, chronic alcohol consumption and tobacco smoking [4].
2. Alcoholic liver disease causes fatty liver and hepatitis leading eventually to cirrhosis and HCC development. Several studies have confirmed a confirmed a dose-dependent effect of alcohol consumption on the risk of HCC and there seems to be no safe limit for the effects of alcohol on the liver. Alcohol acts in synergy with other risk factors for chronic liver disease in the development of HCC [5]. In India, HBV and HCV infection and alcohol consumption are the main causes of HCC [6].
3. Obesity, diabetes and metabolic syndrome have been consistently related to a raised incidence of HCC. This increased risk may be mediated through the development of nonalcoholic fatty liver disease (NAFLD) or these factors may act directly and mediate carcinogenesis without the development of cirrhosis. A significant proportion of patients with nonalcoholic steatohepatitis (NASH) and HCC have noncirrhotic livers [7]. Worldwide the incidence of HCC is likely to increase related to the epidemics of HCV infection, alcohol abuse, obesity, type-2 diabetes mellitus and the metabolic syndrome.
4. Other causes: Aflatoxin exposure, exposure to colloidal thorium dioxide (Thorotrast), primary biliary cirrhosis (PBC), autoimmune hepatitis, Wilson's disease, Budd–Chiari syndrome, hemochromatosis, acute intermittent porphyria, hereditary tyrosinemia, a-1-antitrypsin deficiency and glycogen storage disease type 1. All of these have in common a chronic inflammation related to the hepatocellular injury.

3 Clinical Presentation

HCC is usually diagnosed in an advanced stage. Small tumors amenable to curative treatment are usually discovered in patients under surveillance or incidentally on abdominal imaging for other conditions. Early symptoms are often vague and nonspecific. Due to the liver's large functional reserve HCC may thus progress insidiously and escape early diagnosis.

Right upper quadrant pain, mass and weight loss is the classic clinical triad of HCC. Fever of unknown origin is a common symptom. General symptoms of malignancy such as anorexia, nausea, lethargy and weight loss are often present at diagnosis. Symptoms and signs are both cancer-related and due to the underlying liver disease and function. When advanced the patient may present with hepatomegaly and signs and symptoms of hepatic decompensation like ascites, jaundice, edema, encephalopathy and gastrointestinal bleeding [8]. For many patients the diagnosis of HCC is also the first presentation of their undiagnosed cirrhosis. Variceal hemorrhage is a poor prognostic sign. Jaundice when present could be due to hepatic insufficiency or due to biliary obstruction and this distinction has prognostic significance. Liver failure may occur when the tumor invades the portal vein or the hepatic veins and in rare cases may present with Budd-– syndrome. A rare and dramatic presentation of HCC is tumor rupture presenting with abdominal pain, tenderness and hemodynamic instability. Even more uncommon is the occurrence of paraneoplastic syndromes in HCC like hypoglycemia, erythrocytosis, hypercalcemia and hypercholesterolemia [9].

4 Surveillance and Diagnostic Evaluation

The diagnosis of HCC is primarily radiological and laboratory evaluation can be used as a complement. The use of biopsy is limited to when the diagnosis is uncertain and carries with it the risk of complications like bleeding and needle-track seeding. Diagnostic algorithms and guidelines published by European Association for the Study of the Liver (EASL) and American Association for the Study of Liver Disease (AASLD) have been used in the diagnostic evaluation and treatment of HCC [10–12]. The Japan Society of Hepatology has also published guidelines [13].

4.1 Surveillance

HCC-surveillance involves the application of repeated screening to a group of patients considered high risk, to detect and treat HCC at an early stage and thus improve outcomes. This is usually done at fixed time intervals. Tumor doubling time in HCC varies widely in literature but in most western studies is usually 4–6 months and 6 months is the usual time interval for screening [14]. Factors that should be taken into consideration if a patient is to undergo surveillance include liver function, performance status, comorbidity and compliance so that if HCC is detected, it can lead to a curative treatment. Only then is surveillance meaningful. All patients with cirrhosis regardless of etiology with Child–Turcotte–Pugh (CTP) class A-B should be included in a surveillance program. Patients with CTP class C have poor survival and unless on a transplant waiting list should not be included in surveillance. Noncirrhotic HBV carriers with active hepatitis and chronic HCV patients with advanced fibrosis are also considered high risk and should be followed up [12].

High-quality ultrasound (US) at 6-monthly intervals is the recommended modality by both EASL and AASLD [10, 11]. US has a high specificity and acceptable sensitivity but is highly operator dependent [15]. It is noninvasive and has no complications. The routine use of contrast agents in US is not backed by evidence. Both computerized tomography (CT) and magnetic resonance imaging (MRI) have higher sensitivity and specificity than US but have a high cost and risks including radiation and contrast-related complications. They are not recommended as routine screening modalities and are used only when US is not feasible.

Serum alpha-fetoprotein (AFP) is the most widely tested biomarker in HCC. As a surveillance tool, it however lacks sensitivity and specificity and is not routinely recommended [16]. AASLD recommends use of AFP in conjunction with US for surveillance [12]. When used in combination with US for surveillance, the cut-off value of AFP should be set at 200 ng/mL [4]. The use of other serum markers like des-gamma-carboxyprothrombin (DCP) and glycosylated AFP (L3 fraction) is not recommended for surveillance.

4.2 Diagnostic Evaluation

Detection of HCC at an early stage has a significant impact on improving prognosis and survival in these patients (Fig. 1) [17]. The pathological processes underlying the development of HCC include angiogenesis, changes in cellularity and decrease in the number and function of Kupffer cells. Among these, the vascular alterations seen in the nodules, specifically increased arterial flow and decreased portal flow, are particularly important as far as diagnosis is concerned [18, 19]. While regenerative nodules and dysplastic nodules have a vascularity derived from the portal circulation, HCC development involves neovascularization primarily of arterial derivation. This forms the basis of radiological diagnosis using contrast-enhanced dynamic imaging like contrast-enhanced ultrasound (CEUS), CT and MRI. While US is used as a screening test, it is not diagnostic in the evaluation of HCC. For this, four-phase, multidetector CT (MDCT) and dynamic contrast-enhanced MRI including late hepatic arterial, portal venous and delayed phase imaging, 3–5 min after contrast administration are the recommended radiological modalities for HCC [20–22]. The “radiological hallmark” of HCC during dynamic imaging is the presence of arterial enhancement, followed by wash out of the contrast from the tumor in the portal venous and/or delayed phases [10, 11]. Detailed criteria for radiological diagnosis have been developed by the American College of Radiology and called the Liver Imaging Reporting and Data System (LI-RADS) [23]. These radiological criteria are however applicable only in the presence of cirrhosis and when the lesion size is greater than 1 cm.

Lesions smaller than 1 cm in size should be followed up at 4-monthly intervals with US. When a lesion measures

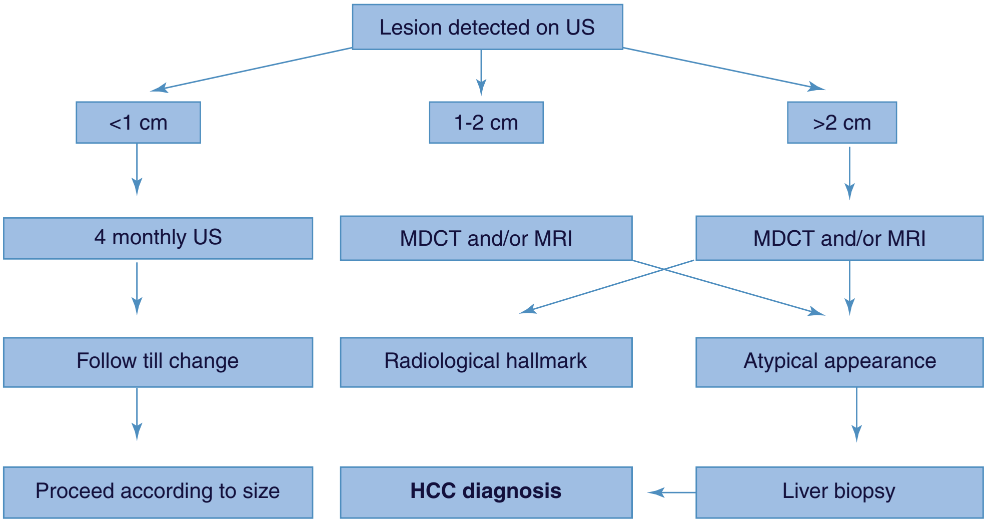

Fig. 1 Diagnostic algorithm for HCC. Adapted from the EASL-EORTC guidelines [10]

1–2 cm and shows the typical HCC "radiological hallmark," i.e., contrast uptake in the arterial phase and washout in the venous/late phase then one imaging modality either CT or MRI can be used for a definitive diagnosis. Most often however a second imaging modality in conjunction with serum AFP and biopsy is needed for diagnosis. If biopsy is negative CT or MRI follow-up is recommended at 3–6-month intervals till changes on imaging are noticed after which a new biopsy is warranted.

Lesions greater than 2 cm in size in the setting of cirrhosis are most often HCC and when the "radiological hallmark" is present, a single imaging modality, either CT or MRI is adequate for a diagnosis. Biopsy may be required if the imaging is atypical. It is worthy of note that approximately 8% of HCC lesion less than 3 cm in size are hypovascular on imaging [24].

In the setting of HCC in a noncirrhotic liver, diagnosis is often made late due to the lack of symptoms. Tumors at diagnosis are large and on imaging are well encapsulated and have a lobulated appearance, showing intense arterial contrast enhancement and sometimes areas of necrosis and bleeding. Even here biopsy maybe sometimes needed for a definitive diagnosis [25].

The complete radiological evaluation in a patient of HCC should include information on the presence and degree of cirrhosis, the presence of portal hypertension and the size, number and location of the tumorous lesions. In addition, vascular or biliary involvement, portal venous thrombosis, lymphadenopathy and the presence of distant metastases should be noted. These variables are essential for accurate staging and have a great impact of the decision making in treatment.

The use of liver biopsy in diagnosis of HCC is not routinely recommended due to risk of bleeding, false negatives and needle-track seeding [26, 27]. Lesions smaller than 1 cm should not be biopsied due to the high risk of sampling error and false negatives. Biopsy should be considered in lesions greater than 1 cm when a diagnosis cannot be established based upon at least two high-quality imaging modalities (MDCT and MRI) according to the EASL-AASLD criteria.

AFP is the most commonly used tumor marker in HCC. It however has both low sensitivity and specificity and is not usually recommended for diagnostic purposes but may be used sometimes as an adjunct. It may, however, be used as a prognostic factor and can sometimes be used to evaluate treatment response.

5 Staging and Treatment Strategy

The value of staging HCC lies in disease prognostication and thus enabling selection of the most appropriate treatment strategy for the patient. It helps in evaluating treatment outcomes and to compare data for research. Outcome in HCC is the product of multiple factors and these should be considered when deciding the treatment. Several staging systems exist but the Barcelona Clinic Liver Cancer (BCLC) staging system is the most widely endorsed and accepted system in the management of HCC and will be discussed in detail later [28].

Before making a treatment decision, three factors must be taken into account when a patient with HCC is staged:

1. The extent of the tumor.
2. The patient's general health status.
3. Liver function and the presence of portal hypertension.

The number and size of nodules, the presence of vascular invasion and the occurrence of extra-hepatic metastases define tumor extent. The size of the tumor is often associated with its propensity for microvascular invasion are definite poor prognostic factors. Both the largest tumor diameter and the total tumor burden have prognostic importance. Micro- and macrovascular invasion of the portal and hepatic veins are indications of the ability of the tumor to metastasize. While macrovascular invasion is often considered a contraindication for transplantation, it is unclear how the presence of microvascular invasion should affect treatment decision-making [29, 30].

A patient's general health status plays an important role in determining which treatment can be offered to a patient. The health status includes both performance status and the presence of symptoms. The ECOG/WHO scale was developed by the Eastern Cooperative Oncology Group (ECOG) and is widely used as a measure of the patient's performance status and is included in BCLC staging system [31, 32].

Liver function is most commonly evaluated by the Child–Turcotte–Pugh (CTP) score. It is a simple and widely used grading system for liver function and categorizes patients into three groups A, B and C according to deteriorating liver function (Table 1). A big disadvantage of CTP score is the presence of subjective parameters. Other methods like the MELD score (Model for End-stage Liver Disease), measurement of portal pressure, indocyanine green retention rate measurement have been used with variable success [33, 34]. The MELD score was adopted by the United Network for Organ Sharing (UNOS) in 2002 for prioritization of patients awaiting liver transplantation but it has been criticized for failing to classify patients with advanced liver disease correctly. The measurement of indocyanine green retention at 15 min (ICG R-15) is a well-established method used to estimate liver function especially in Asian countries and is recommended in the decision making for both indication and extent of surgery [4]. Portal hypertension as a prognostic factor has been validated. Direct indicators like measuring the hepatic venous pressure gradient (HVPG) and evaluating for indirect indicators of portal hypertension, viz., esophageal varices, splenomegaly and platelet count <100.000/mm^3 are recommended before surgery [10].

Table 1 The Child–Turcotte–Pugh (CTP) scale

Measure	1 point	2 points	3 points
Total bilirubin, µmol/L (mg/dL)	<34 (<2)	34–50 (2–3)	>50 (>3)
Serum albumin, g/dL	>3.5	2.8–3.5	<2.8
Prothrombin time, prolongation (s) *or* INR	<4.0 <1.7	4.0–6.0 1.7–2.3	> 6.0 >2.3
Ascites	None	Mild (or suppressed with medication)	Moderate to severe (or refractory)
Hepatic encephalopathy	None	Grade I–II	Grade III–IV

CTP Class obtained by adding score for each parameter
Class A—5–6 points
Class B—7–9 points
Class C—10–15 points

5.1 Staging Systems in HCC

Over the years multiple staging systems have been developed and used all over the world. Since 1985, when the Okuda staging system was first published, combining both parameters for tumor and liver function, at least 18 staging systems and guidelines have been published, each having their strengths and drawbacks [35, 36].

For most cancer types, the tumor–node–metastasis (TNM) system is the standard for staging, reporting and comparison of data. In HCC, the eighth TNM edition of the American Joint Committee on Cancer/International Union Against Cancer is currently used [37]. A major drawback with the TNM system in HCC is that it does not include liver function or the patients' health status and that it can be applied only in resected or transplanted patients in the postoperative setting. Its use preoperatively in staging and treatment decision-making is thus limited. The TNM staging system is used mainly for pathological staging and has been validated for this purpose [38].

The Okuda staging system, Cancer of the Liver Italian Program CLIP) score, Barcelona Clinic Liver Cancer (BCLC) stage, French GRETCH, Chinese University Prognostic Index (CUPI), Japanese Integrated Scoring (JIS), Tokyo score and Hong Kong Liver Cancer (HKLC) systems are some of the systems in use. Of these, the BCLC staging system is the most established and validated [39]. The EASL–EORTC and the AASLD guidelines endorse the BCLC classification [10, 11]. The BCLC uses tumor extent, liver function and the patients' health status to categorize patients into 5 groups where groups 0 and A are amenable to potentially curative treatment, groups B and C can receive active palliative treatment and group D, just symptomatic treatment (Fig. 2) [39, 40].

According to the BCLC system, *very early stage HCC* (BCLC stage 0) is defined as the presence of a single tumor <2 cm, without vascular invasion/satellites in patients with ECOG-0 and a with a CTP class A. *Early stage HCC* (BCLC stage A) includes patients with single tumors >2 cm or 3 nodules <3 cm of diameter, with ECOG-0 and CTP class A or B [10]. These patients can be offered curative treatments, including resection, transplantation and ablation achieving good results with median overall survival (OS) more than 60 months and 5-year survival of 50– 75% [10, 41, 42].

The *intermediate stage* (BCLC stage B) comprises patients with multifocal HCC without macrovascular invasion, or extrahepatic spread, with CTP A or B and do not have cancer-related symptoms, with ECOG 0. These patients may be offered palliative treatment, such as trans-arterial

chemoembolization (TACE) and a median survival of up to 20 months with the best responders going up to 36–45 months [43].

The *advanced stage* (BCLC stage C) includes patients who present with macrovascular invasion or extrahepatic spread with lymph node involvement or metastases. Patients are usually symptomatic and have ECOG 1–2. These patients have a very poor prognosis with a median survival of 6 months. This prognosis has been improved somewhat by the introduction of Sorafenib, a multityrosine kinase inhibitor now used in advanced cases and discussed later [44].

Finally, patients with poor general status (ECOG 3–4) and CTP C due to extensive tumor involvement are considered *end stage HCC* (BCLC stage D). Prognosis is dismal and only symptomatic treatment can be offered. Here median survival is 3–4 months [28].

Hong Kong Liver Cancer classification was proposed in 2014 based on the results from a single center cohort of 3856 patients of HCC, predominantly associated with HBV infection. This system more effectively deals with the problems of heterogeneity in the BCLC B and C groups and the rigid allocation of treatment options. It allows for more aggressive management with surgery as an option for BCLC B and TACE as an option for BCLC C groups. It is considered more suitable for the Eastern population with predominantly HBV associated disease [45].

6 Treatment

Decision-making in HCC treatment should always be made in a multidisciplinary setting with hepatologists, surgeons, oncologists, radiologists, interventional radiologists and pathologists involved in the process. Potentially curative treatments in HCC include liver resection, liver transplantation and ablation while palliative treatments include TACE and Sorafenib. Choosing the optimal treatment is controversial and is reflected in the recommendations of the various international HCC guidelines. Deciding which is the optimal is often a matter of debate but resection and transplantation achieve the best outcomes with 5-year survival between 60% and 80% [21]. The BCLC staging system or similar is usually used as a guide to allocate treatment but the final choice depends on local tradition, competence and available resources. Regardless of the treatment algorithm used, the three important factors, tumor extent, health status and liver function should be given careful consideration and the patient staged appropriately.

6.1 Liver Resection

Along with transplantation, resection forms the mainstay of treatment in patients with early stage tumors. It is the treatment of choice in patients with preserved liver function (CTP A), good performance status and when resectability has been evaluated in terms of tumor burden and function of the liver remnant [4].

In noncirrhotic patients, resection is the treatment of choice, with major hepatectomy being performed to achieve "R0" status, with good perioperative outcomes and acceptable survival [46]. In the setting of cirrhosis, strictly following most current treatment guidelines, resection can be offered only to patients with early stage HCC (BCLC stage 0-A). In practice however, both intermediate and advanced stage tumors (BCLC stages B and C) with good performance status and preserved liver function (CTP A and early B) are often considered for resection with good results [47, 48]. In the report by Torzilli et al., 5-year survival rates of 57% and 38% were reported for BCLC B and C patients respectively [47]. Indeed, the BCLC criteria are regarded as too restrictive especially in Asian countries with the Japanese, Korean and Hong Kong algorithms all recommending a more radical approach in adopting resection for more advanced tumors [4].

Serum bilirubin, cirrhosis, esophageal varices, tumor size and macrovascular invasion are independent prognostic factors for overall survival in resected patients [47]. Intrahepatic macrovascular portal or hepatic venous invasion is not a contraindication for surgery but spread outside the liver including lymph node metastases are associated with very poor survival and resection is usually not recommended. In the setting of cirrhosis resection should be considered only when the patient has a good liver function (CTP A) due to the high risk for postoperative liver failure when a major resection is performed.

Complete oncological clearance ideally warrants an anatomical resection for negative margins. Most micrometastases occur within a 2-cm margin from the tumor and the recommendation is to strive for this margin during resection. However, this may not be always possible either due to location of the tumor or due to the need to preserve as much parenchyma as possible in cirrhotic patients. Whether segmental resection is better than atypical resection in HCC is controversial, but an attempt to perform an anatomical resection should always be made [49]. To this end, high quality preoperative imaging in surgical planning is indispensable. Technological advances in liver surgery especially in transection techniques like the ultrasonic dissector have found widespread application but local tradition and availability usually guides which method is used. Laparoscopic resection for HCC is safe and feasible in selected patients and is usually recommended for peripherally located tumors <5 cm in size [50].

Preoperative strategies to increase the future liver remnant (FLR) have been used for HCC with methods like portal vein embolization or ligation (PVE/PVL), sequential TACE and PVE, radioembolization and associated liver partition and portal vein ligation for staged hepatectomy (ALPPS) being used to improve resectability [51]. In the cirrhotic patient with HCC these approaches are however of questionable value due to uncertain hypertrophy of the FLR.

Blood loss during liver surgery has a profound impact on morbidity and mortality. Low central venous pressure (CVP) maintenance, intermittent Pringle maneuver and the use of techniques like the "anterior approach," "Hepatic vascular exclusion" and the "liver hanging maneuver" have all been used to reduce blood loss during liver resection [8].

6.2 Liver Transplantation

Orthotopic liver transplantation (OLT) is the most definitive treatment for HCC removing not only the tumor radically but also the diseased liver and with it. This reduces the risk for recurrence as well as cirrhosis-related morbidity and mortality. Transplantation is the treatment of choice for HCC in patients with poor liver function (CTP B and C), when an organ is available [4].

The well-established "Milan criteria" are widely used as patient selection criteria in terms of tumor burden [52]:

- Solitary nodule ≤5 cm in diameter or,
- ≤3 nodules, ≤3 cm in diameter,
- And without radiological evidence of vascular invasion or distant metastases.

The Milan criteria have been incorporated into the BCLC algorithm and by the UNOS pretransplant staging for organ allocation in the US but are widely regarded as too restrictive [4, 10].

The University of California, San Francisco (UCSF) criteria is the most accepted extension of the Milan criteria and has comparable outcomes [53]:

- Single tumor ≤65 mm in diameter,
- Or 2–3 tumors, each ≤45 mm with accumulative tumor size ≤ 80 mm,
- And without radiological evidence of vascular invasion or distant.

Macrovascular invasion is usually considered a contraindication to transplantation.

In cirrhotic patients with early HCC with good liver function (CTP A) where resection is usually the first choice of treatment, the use of transplant as an alternative is controversial. In Western countries, in the presence of portal hypertension liver transplant is recommended to these patients. In Asia, even if portal hypertension is present these patients with early tumors are usually resected with equivalent outcomes [4, 54]. Decision-making in this situation should always be made in a multidisciplinary setting weighing the pros and cons in each individual case.

The major drawback in offering liver transplantation is the limited availability of organs and long transplant waiting lists with the inherent risk of disease progression leading to drop outs. To circumvent this problem several strategies have been proposed. Living donor-related transplant (LDLT) has the advantage of practically no waiting list if a suitable donor is available. However, it does have an inherent risk of morbidity to the donor with an approximately 2% risk of severe complications and 0.3% mortality [10]. Some studies report an increased recurrence rate in LDLT as compared to deceased donor-related transplant (DDLT) while others report no difference in survival outcomes [55]. As of today, LDLT should be limited to centers of excellence in hepatic surgery and transplantation.

To minimize the drop-outs in the waiting period, the use of "bridge-to-transplantation" therapies in the neoadjuvant setting such as TACE, ablation or radioembolization have gained popularity. Though helpful in reducing the drop rate, their effect on long-term outcomes remains to be seen and further study in this area is needed [56]. Another alternative to primary OLT is the policy of salvage liver transplantation (SLT) in which the patient undergoes surgical resection first and a transplant is offered later for recurrence or due to deterioration of liver function. Outcomes of SLT after resection for HCC may be comparable to primary OLT and is still a feasible option in centers with resource constraints for transplant [57].

6.3 Local Ablation

Local ablative techniques are employed to locally destroy tumors in the liver. Local ablation is recommended for early stage tumors, i.e., CTP class A or B patients with ≤3 tumors each ≤3 cm in diameter (BCLC stage 0-A) in patients who are not suitable candidates for surgery due to age, associated comorbidities, location of the tumor and to some extent liver function [4, 10]. The advantage of local ablation is that less "normal" liver parenchyma is sacrificed and that most often it can be performed percutaneously, thus avoiding open surgery. On the other hand, the drawbacks include possible incomplete tumor destruction, risk for tumor seeding and the limit on the size of tumors that can be ablated. Tumors close to the liver hilum, the central bile ducts and peripheral HCCs close to other organs pose a problem and sometimes preclude ablation. The commonest modalities are radio frequency ablation (RFA), microwave ablation (MWA) and percutaneous ethanol injection (PEI).

PEI was the first described method and was for a long time the standard for local ablation whereby alcohol was injected under image guidance to induce coagulative necrosis in the tumor. PEI has however been superseded by RFA and MWA as the most widely used ablative techniques for HCC due to a high local recurrence rate and inferior survival [58]. It is still, however, used when thermal techniques cannot be applied or as a complement to them.

Both RFA and MWA use thermal energy to induce coagulative necrosis in the tumor. RFA is the most widely studied and available modality for ablation and produces a "safety ring" around the tumor most likely destroying even small microsatellites around it [10]. MWA has an advantage that peritumoral vessels do not reduce its efficacy and the treatment time is shorter than RFA. Both RFA and MWA can be performed percutaneously (US- or CT-guided), laparoscopically and during open surgery depending upon the individual case. Advances in radiology like multimodality fusion imaging have the potential to improve outcomes in ablation. These methods have a low rate of complications and ablation can easily be repeated in case of incomplete effect or recurrence. Essentially RFA and MWA have similar results especially with the introduction of newer generation MWA systems [59]. To evaluate the effect of ablation radiology is usually recommended 4 weeks after the procedure. If done earlier, the reactive hyperemia surrounding the ablation zone can be misinterpreted as incomplete ablation.

Irreversible electroporation (IRE) is a nonthermal ablation technique using electric pulses to induce cell death, at the same time preserving the structural integrity of bile ducts and vessels. IRE seems to be useful for tumors near the major blood vessels or bile ducts but data on this technique is scare [4].

Comparing outcomes after surgery and local ablation is not easy. There have been a several studies comparing ablation and resection for early HCC and the evidence shows that resection has better long-term survival and lower recurrence rate as compared to ablation [60]. Liver resection is however associated with longer hospital stay and higher rate of complications but should be recommended as the first-hand choice. Other ablative methods like cryoablation, laser ablation and high-intensity focused ultrasound (HIFU) have been used but have not gained widespread application [59].

6.4 Transarterial Chemoembolization (TACE) and Other Transcatheter Therapies

TACE is a palliative treatment recommended for HCC in patients with unresectable, large/multifocal HCCs who do not have vascular invasion or extrahepatic spread and with good performance status and relatively preserved liver function (CTP A or B) [4, 10]. The principle of TACE is based on the fact that HCC receives it blood supply almost entirely from the hepatic artery. Thus, chemotherapeutic agents can be delivered in a targeted fashion, and then followed by embolization of the arterial supply. When infusion of chemotherapy is performed without embolization it is called transarterial chemoinfusion (TAI), whereas embolization with radioactive microspheres is called transarterial radioembolization (TARE) or selective internal radiation therapy" (SIRT) [4].

Different chemotherapeutic agents have been used for TACE but the commonest is Doxorubicin. It most often mixed with the contrast agent, lipiodol and delivered through a catheter superselectively placed in the arterial supply of the tumor. After this embolization is carried out by particles like gel foam. Doxorubicin can also be bound to microspheres (drug eluting beads) instead of lipiodol and the procedure is then called DEB-TACE and has fewer side effects than conventional TACE because of less systemic absorption of the chemotherapeutic agent [61]. The protocol for TACE is not standardized and varies depending on the local tradition but is most often repeated at 1–3-month intervals as long as it is technically possible. The first evaluation is recommended by CT or MRI 1 month after treatment.

TACE has demonstrated significant survival benefit in selected patients with intermediate stage HCC (BCLC stage B) but results have been disputed in several review articles and meta-analyses [62]. TACE can also be performed in smaller tumors unsuitable for ablation because of comorbidity or tumor location. TACE can also be combined with other local ablative approaches in suitable patients and used as a "bridge-to-transplantation" as discussed earlier.

The contraindications to TACE include decompensated cirrhosis, jaundice, encephalopathy, refractory ascites, impaired portal venous flow, extensive bilateral tumor involvement, malignant portal vein thrombosis, large tumor >10 cm, severe comorbidity etc. [62]. Postembolization syndrome may occur after TACE and symptoms include, fever, abdominal pain and nausea and is often self-limited and easily treatable.

SIRT uses the infusion of radioactive substances such as 131-Iodine-labeled Lipiodol or microspheres containing yttrium-90 (Y90) or similar agents to deliver radiation directly to the tumor. Currently, the most popular technique uses resin or glass microspheres coated with Y90, a ß-emitting isotope.

SIRT is performed in a lobar, sectorial, or segmental approach according to tumor size and location. In patients with HCC developed on chronic liver disease, whole-liver treatment in one session is discouraged. Because of the minimal embolic effect of Y90 microspheres, treatment can be safely used in patients with portal vein thrombosis [63]. Compared to TACE, SIRT induces less toxicity, provides significantly longer time to progression and better tumor control and maintains higher quality of life, although it does not provide longer survival [64, 65].

6.5 Systemic Therapy

Sorafenib, is an oral multikinase inhibitor of Raf, vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), c-kit, Flt-3 and RET used for the treatment of patients with advanced HCC (macrovascular invasion/metastatic, BCLC stage C) in patients with good liver function (CTP A and selected CTP B) [4, 44, 66]. Results of the European SHARP trial and an Asia-Pacific trial have shown that Sorafenib prolonged survival (increased median survival by 2–3 months) in patients regardless of age, performance status and extent of the tumor [44, 67]. Sorafenib is usually given at a dose of 400 mg twice a day. Side effects include included diarrhea, fatigue, hand–foot skin reaction and rash/desquamation.

Post the advent of Sorafenib, a number of targeted agents have being evaluated in studies to improve survival with Sorafenib as a comparator arm. Till date, the only other molecule which has been found comparable to sorafenib is Lenvatinib, an inhibitor of VEGF receptors 1-3, FGF receptors 1-4, PDGF receptor α, RET and KIT [68].

Regorafenib is an oral diphenylurea multikinase inhibitor targeting angiogenic stromal and oncogenic receptor tyrosine kinases. It had been approved for the treatment of patients with advanced HCC previously treated with Sorafenib and has been shown to improve survival as compared to placebo [69]. The most common adverse events include fatigue, diarrhea, hypertension and hand–foot skin reaction.

6.6 Immunotherapy

Nivolumab, a fully human IgG4 monoclonal antibody and programmed cell death protein-1 (PD-1) immune checkpoint inhibitor, has been evaluated in a phase I/II open-label, non-comparative, dose escalation and expansion trial (CheckMate 040). Impressive results with Nivolumab resulting in OS of 66% at 6 months and 9 months, and median OS of 15.0 months were seen [70].

The use of systemic chemotherapy with agents like Doxorubicin in the adjuvant setting has not shown any survival advantage and is not recommended [71].

6.7 Stereotactic Body Radiation Therapy (SBRT)

SBRT involves highly precise delivery of high dose of radiation in 3–6 fractions such that it has potential of higher cell kill and ablation of the liver tumor while sparing the normal liver parenchyma. SBRT may be used in patients who have failed other locoregional therapies. It has low toxicity and acceptable local control rates in well-selected patients [72]. It can be used as a stand-alone treatment or in combination with other therapies like TACE and ablation. It may also be used has a bride-to-transplant therapy. Studies are ongoing to further define the role of SBRT in HCC treatment.

6.8 Evaluation of Treatment Response and Follow-Up

HCC if not treated by resection or transplantation responds usually by necrosis to other treatment modalities. This fact forms the basis for the radiological evaluation of treatment effect. The Response Evaluation Criteria in Solid Tumors (RECIST) criteria were subsequently modified by the EASL (mRECIST) and are now considered the gold standard for measuring tumor response during treatment for HCC [73]. Viable tumor is defined as uptake of contrast agent in the arterial phase.

After curative treatment, the initial response evaluation should be performed at 4 weeks. Thereafter, clinical, laboratory and radiologic evaluation using dynamic contrast-enhanced CT or MRI studies every 3 months the first 2 years and thereafter every 6 months is recommended [74]. When recurrence is detected, the patient should be restaged and curative treatment offered if appropriate. Follow-up of HCC patients treated with palliative intention is usually recommended at 3-monthly intervals.

Gastric Cancer

Manish S. Bhandare and Anant Ramaswamy

Abbreviations

CT	Computerized tomography
DCF	Docetaxel–Cisplatin–5 Fluorouracil
ECX	Epirubicin/Cisplatin/Capecitabine
EGC	Early gastric cancers
EMR	Endoscopic mucosal resection
ESD	Endoscopic submucosal dissection
EUS	Endoscopic ultrasonography
FLOT	Fluorouracil/leucovorin
FOLFIRI	5 Fluorouracil–Irinotecan
GC	Gastric cancer
GEJ	Gastroesophageal junction
JGCA	Japanese Gastric Cancer Association
RFS	Recurrence-free survival

1 Introduction

Gastric cancer (GC) and its management remain an important issue in the world of oncology, owing to a high relapse rate, even after curative treatment. Worldwide, most countries are experiencing a steady decline in the incidence of GC. Contrary to this observation, the projected incidence for India is on increasing trend.

Although a variety of tumors, i.e., adenocarcinoma, lymphoma, carcinoid and sarcoma, are known to occur in stomach, this chapter will focus on gastric adenocarcinomas, which account for more than 90% of all cases of GC.

The reported overall 5-year survival rates for GC are between 20% and 25%, across all stages in most industrialized nations. Stage of disease at time of diagnosis is clearly a single most important factor influencing survival. Patients diagnosed to have earlier stages of gastric cancer have a distinct advantage as against those with higher-stage disease.

2 Epidemiology: Indian and Global Scenario

As is the case for many cancers, the epidemiological distribution of GC demonstrates a marked variation in regional incidence, with as much as a ten-fold difference between the highest- and lowest-risk populations. The highest incidence is found in countries from South East Asia, i.e., Japan, China and South Korea [1]. Globally, India ranks at a much lower level and is considered as a low incidence country. GC in India is counted among the top five common malignancies, being the fifth most common cancer for men while sixth most common for women [2]. The case fatality rate is high, and hence, it is the second most common cause of cancer-related death among patients with malignancy in the age group between 15 and 44 [3, 4].

Unique feature of GC in India is the presence of a wide geographic variation in its incidence. Although only 7% of the population is covered in various registries providing data (NCR-National Cancer Registry, Hospital or population-based registries), the highest incidence in India is recorded from the district of Aizawl from Mizoram state accounting for 62.2/100,000 cases. The state with second most common incidence is Tamil Nadu from South India.

With highest burden of this disease in South East Asia, the annual burden of GC is likely to increase up to 1.8 million new cases and the GC deaths are likely to reach to 1.3 million annually by year 2040.

3 Risk Factors for Gastric Cancer

Several factors are known to be associated and they may be different depending on the location of the tumor within stomach, e.g., proximal or distal GC. History of gastric dysplasia or adenoma, chronic atrophic gastritis and prior gastric surgery are considered as important risk factors. Irrespective of the geographical region, the worldwide incidence is at least two fold more common in males as compared to females.

For noncardia, i.e., distal or body cancers, chronic infection with *H. pylori* is the commonest risk factor [5]. Alteration of the cell cycle check points and mutations in the tumor suppressor genes related to the *H. pylori* infection are thought to be the prime reasons for carcinogenesis [6]. Dietary habits such as high intake of pickled, smoked, salted, or preserved foods and a low intake of fruits and vegetables may increase the risk of GC [7, 8]. Apart from the dietary factors, tobacco in any form (particularly smoking) is associated with development of GC with predilection of proximal stomach or gastric cardia [9]. Overweight status and obesity are also known to increased GC risk [10]. About 10–15% of cases with GC are associated with familial predilection (5–10%) or inherited syndromes (3–5%) [11]. GC history in a siblings or parent can result in two-fold increased risk [12, 13]. Inherited cancer predisposition syndromes with strongest association for GC are seen in hereditary nonpolyposis colon cancer and hereditary diffuse gastric cancer syndrome (Table 1).

Table 1 Hereditary syndromes with increased risk of developing gastric cancer

Syndrome	Gene(s)	Pattern of inheritance
Hereditary diffuse gastric cancer	CDH1	AD[a]
Lynch syndrome (LS)	EPCAM, MLH1, MSH2, MSH6, PMS2	AD[a]
Juvenile polyposis syndrome (JPS)	SMAD4, BMPR1A	AD[a]
Peutz–Jeghers syndrome (PJS)	STK11	AD[a]
Familial adenomatous polyposis (FAP)/attenuated FAP (AFAP)	APC	AD[a]
Ataxia-telangiectasia	ATM	AR[b]
Bloom syndrome	BLM/RECQL3	AR[b]
Hereditary breast and ovarian cancer syndrome	BRCA1, BRCA2	AD[a]
Li–Fraumeni syndrome	TP53	AD[a]
Xeroderma pigmentosum	7 different genes	AR[b]
Cowden syndrome	PTEN	AD[a]

[a]*AD* autosomal dominant, [b]*AR* autosomal recessive

Apart from the *H. pylori* infection, Epstein–Barr virus infection is also associated with GC development. Its role in carcinogenesis, however, remains unclear [14, 15].

Socioeconomic status, geographical region, Menetrier disease (hypertrophic gastropathy), pernicious anemia and blood group A are the other factors associated with increased risk.

4 Clinical Presentation

In the early stage, often patients do not exhibit any symptoms. Dyspepsia (indigestion, bloating, heartburn, etc.) is often a commonly associated symptom with GC. In more advanced stage, vomiting and nausea, bleeding (hematemesis and/or melena), abdominal pain, lump in epigastric region, unexplained weight loss, loss of appetite and early satiety, can be experienced by the patients. Gastroesophageal junction or proximal gastric tumors can produce dysphagia as an early symptom. Most often, a combination of the above mentioned symptoms are present at the diagnosis.

For advanced, large distal stomach tumors, following signs may be present.

- Lump in the epigastrium.
- Peristalsis can be seen (Left to right) in the left hypochondrium.
- Succussion splash and borborygmi also be noted in obstructing tumors.
- Left supraclavicular adenopathy (Virchow’s node).
- Left axillary node (Irish node).
- Periumbilical nodule (Sister Mary Joseph’s node).
- Ovarian metastasis (Krukenberg’s tumor).
- Mass in the pouch of Douglas on rectal examination (Blumer’s shelf).
- Fluid thrill secondary to ascites.
- Palpable mass in the right hypochondrium (liver metastasis).

5 Evaluation and Work-Up

5.1 Tumor Markers

None of the tumor markers are considered ideal for diagnosis of GC, owing to a low rate of sensitivity and specificity. The serum levels of the following markers may be elevated at presentation [16–18],

- CEA (carcinoembryonic antigen),
- CA 19-9 (carbohydrate antigen 19-9),
- CA 125 antigen (CA 125) and
- CA 72 A (cancer antigen 72-4)

Although the tumor markers are not helpful for diagnosis, if the baseline levels are elevated, their serial rise in the follow-up may be useful to detect disease recurrence [19, 20].

Increases in serum pepsinogen II or decreases in the pepsinogen I: pepsinogen II ratio have been used in population screening programs to identify patients at increased risk for GC but are insufficiently sensitive or specific for establishing a diagnosis in an individual patient.

5.2 Endoscopy

Identification of primary tumor, anatomic localization and tissue diagnosis are best possible by a simple endoscopy (UGI—Upper GI Endoscopy).

During endoscopic assessment, any lesion suspicious for malignancy should undergo biopsy.

Multiple (at least 6–8) biopsies from the lesion are recommended as this increases the diagnostic yield to more than 98% as compared to a single biopsy [21].

5.2.1 Endoscopic Ultrasonography (EUS)

For accurate T staging (knowing the depth of invasion), EUS is the most sensitive investigation [22]. Most benefit is obtained in in detecting T1 lesions. Conventional CT scan techniques could not categorize T stage as reliably as EUS in comparative studies [23, 24]. However, MRI or multidetector 3-D CT scan may perform equally well as EUS to accurately assess T stage [25, 26].

Although EUS has been recommended for pretreatment evaluation in patients without any suspicion of metastatic (M1) disease on conventional CT imaging, in practice it is performed when early GC is suspected on endoscopy and CT scan [1] to identify patients suitable for endoscopic resection or [2] for upfront surgery.

5.3 Pathology

The most commonly used histological classification systems are the Lauren and WHO schemes [27, 28]. As per the Lauren classification, GCs are divided into diffuse and intestinal histological subtypes. Most diffuse GCs are characterized by poor differentiation, have poorly cohesive tumor cells and lack any gland formation. The intestinal types generally are well or moderately differentiated and can form glands. The WHO classification takes into consideration the predominant morphological appearance on histology and has five types, i.e., tubular, papillary, mucinous, poorly cohesive and rare variants. In general, the tubular and papillary types in WHO classification correlates to the intestinal type in the Lauren's classification and have more favorable outcomes, and the poorly cohesive type can be related to the diffuse Lauren's type which has poorer outcome [29].

5.3.1 Molecular Classification

According to the genomic profiling studies by TCGA (The Cancer Genome Atlas) group, four subgroups of primary gastric adenocarcinoma has been identified [30]:

- Positive for Epstein–Barr virus (9%)
- Microsatellite unstable tumors (22%)
- Genomically stable tumors (20%)
- Chromosomally unstable tumors (50%)

Other classifications have also clearly demarcated molecular subgroups with differing clinical characteristics and survival outcomes [31]. Although at present the utility of this classification in the clinical practice is limited, these subtypes may be useful for determining the prognosis more accurately, together with the TNM stage and also lead to developing personalized treatment strategies in future.

5.4 Radiology

A contrast-enhanced computerized tomography (CT) scan is often the initial staging test after confirmation of diagnosis of GC (Figs. 1 and 2). Visceral metastatic disease, e.g., lung, liver, adnexa and distant lymph nodes, can be easily detected on CT scan. Also, it provides information regarding the local extent of the tumor, involvement of adjacent structures (left lobe of liver, pancreatic head, invasion of porta hepatis, etc.) and helps predicting resectability. However, it lacks sensitivity in detecting smaller visceral spread (<5 mm) and peritoneal spread, even using modern CT techniques [32]. PET-CT scan was not considered useful in primary evaluation of GCs as the diffuse type (signet ring cell tumors) lack any FDG activity. However, its role in preoperative evaluation is developing. Integrated PET-CT can be used for knowing the local tumor extent and is more sensitive for detecting metastatic disease [33]. Hence, integrated PET/CT has been suggested in the NCCN guidelines as a part of initial evaluation of GC.

Detection of peritoneal disease still remains a problem, even with the integrated PET-CT, and hence, it cannot substitute staging laparoscopy [34].

5.5 Staging Laparoscopy (SL)

Although SL requires anesthesia and is an invasive surgical procedure to be performed as a part of diagnostic work up, it remains the most sensitive test to detect peritoneal metastasis. Biopsy of any suspicious nodule should be performed during SL along with collection of peritoneal lavage fluid for cytological examination. In patients with radiological T3/T4 tumors without any metastatic spread on imaging, SL upstages the disease which leads to change in management plan in about 20–30% cases [35, 36]. Hence, SL is a part of

routine evaluation for all patients with locoregionally advanced disease (cT3/T4, N+ disease).

5.6 Referrals Including Genetic Counseling

As discussed previously, about 5–10% GCs have a familial association and about 3–5% are a part of inherited cancer syndrome.

Genetic counseling or testing is recommended in the following situations [37]:

- Existing GC gene mutation in the family
- GC in one family member at a young age (< 40 years of age), or
- GC in 2 first/second-degree relatives with one diagnosis before age 50, or
- GC in 3 first/second-degree relatives independent of age, or
- GC and breast cancer in one patient with one diagnosis before age 50, or
- GC in one patient and breast cancer in one first/second-degree relative with one diagnosis before age 50

The malignancy risk assessment during genetic counseling should include a complete family history of all medical and surgical treatments. A detailed and focused physical examination should be performed along with psychosocial assessment. Also, the available mental and financial support in the event of a problem should be assessed. Following which an informed consent is obtained and necessary genetic tests are ordered.

6 Principles of Management

The management of GC requires a multidisciplinary approach. All patients are staged according to the AJCC classification [38]. Once clinical staging is complete, appropriate treatment plan is established in the multidisciplinary clinic and is often with curative intent for patients with stage I, II and III disease, while the approach is palliative for most cases with stage IV disease.

Radical surgery remains at the cornerstone in the management of GC. Neoadjuvant chemotherapy (perioperative chemotherapy) has an established role in patients with locoregional disease and is considered as standard of care outside South East Asia. Postoperative chemotherapy or postoperative chemo radiation, are alternative approaches for these tumors.

GC can be categorized into following groups for describing various treatment approaches,

6.1 Early Gastric Cancers (EGC) [T1a/T1b N0/N+ M0]

EGC is defined as cancer which is confined to the mucosa and submucosa regardless of lymph nodes status. Following are treatment options depending on the lesion characteristics, presence of LN status and availability of expertise:

- Endoscopic resection [39]: endoscopic mucosal resection (EMR), endoscopic submucosal dissection (ESD).
- Surgery (radical gastrectomy/local resection) [40, 41].
- Antibiotic treatment for eradication of *Helicobacter pylori* [42].
- Adjuvant chemotherapy for patients with N+ disease.

6.2 Gastric Cancer with Locoregional Disease [T2-T4 N+ M0]

Treatment strategies are:

- Perioperative chemotherapy with radical D2 gastrectomy (as per MAGIC protocol) [43].
- Radical D2 gastrectomy followed by adjuvant chemoradiotherapy [44–46].
- Radical D2 gastrectomy with adjuvant chemotherapy [47, 48].

6.3 Advanced Gastric Cancers [Unresectable T4 N+ or M1]

Depending on the overall health and performance status of the patient, following are options:

- Surgery: Palliative gastrojejunostomy, palliative gastrectomy (highly selected cases with gastric outlet obstruction or persistent tumor bleed unresponsive to other mode of bleeding control).
- Palliative chemotherapy: With intent of improving QOL and survival.
- Palliative radiotherapy: For pain control and for controlling chronic/slow tumor bleed.
- Symptomatic palliation of pain and ascites.

7 Surgical Management

The aim of surgery for GC surgery is to obtain a complete tumor removal with adequate margins. The involved part of the stomach is removed resecting approximately 5 cm of normal appearing, healthy stomach proximal as well as distal to the tumor. This 5 cm margin is not possible distally in antropyloric tumors and proximally for GE junction or cardia tumors. At these instances, a 1 cm margin at duodenum or esophagus respectively, is acceptable. However, it should always be confirmed on intraoperative frozen section. The standard lymph node clearance should be D2 dissection. As per the tumor location within stomach; distal subtotal, proximal or total gastrectomy are accepted as oncologically sound procedures (Fig. 3).

- Total gastrectomy: It is performed for tumors involving entire stomach (linitis plastica) or body tumors with involvement of lesser curvature (proximal to incisura) or large/bulky proximal tumors with significant peri gastric lymph node involvement.
- Distal subtotal gastrectomy: Performed for tumors involving antrum-pylorus, distal body and tumors not extending proximal to incisura.
- Proximal gastrectomy: Is an option for early stage tumors of the cardia, proximal body without significant perigastric lymphadenopathy.

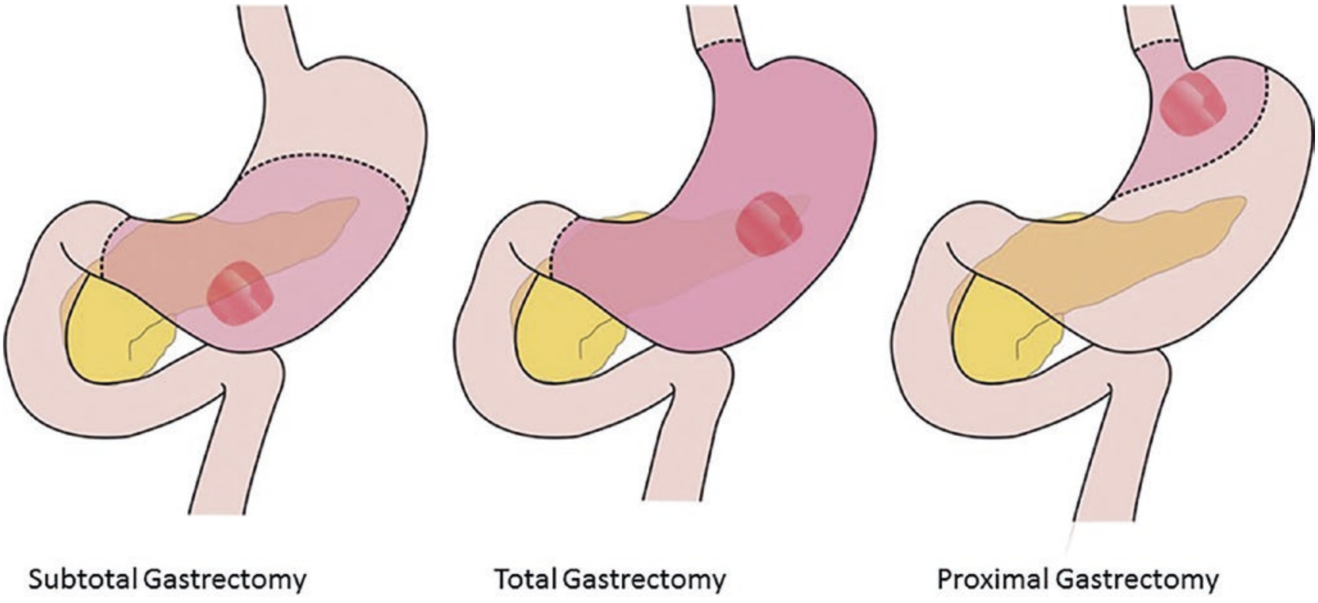

Fig. 3 Types of radical gastrectomy

7.1 Surgery for Distal Tumors

For tumors involving distal part of the stomach, the available evidence comparing distal subtotal vs. total gastric resection did not show any survival difference [49, 50]. The advantage with a more conservative distal subtotal gastrectomy is to offer a better QOL, maintenance of nutritional status and weight as compared to total gastrectomy and hence is the standard of care for tumors in this location.

7.2 Surgery for Proximal Tumors

According to the Japanese Gastric Cancer Treatment Guidelines (2010), both proximal and total gastrectomy can be options for early-stage disease involving the cardia or proximal body [51]. In general, proximal gastrectomy should be avoided in more advanced tumors with regional lymphadenopathy as D2 dissection is not possible with proximal alone resections. However, the available evidence is not robust, and some reposts mention feasibility and oncological safety of this procedure even in locally advanced proximal GCs after neoadjuvant chemotherapy (NACT), when it is technically feasible [52]. Still, a total gastrectomy is favored for the following reasons:

- Biliary reflux causing esophagitis and later stricture can be a known complication with proximal gastrectomy; however, it is never a problem with the Roux-n-Y anastomosis performed during the total gastrectomy [53].
- Perigastric lymph node stations, namely station 4, 5 and 6 are left behind during proximal gastrectomy and can compromise oncological safety.

7.3 Surgery for Early Gastric Cancer (EGC)

EGC was first defined in 1962 by the Japanese Society of Gastroenterological Endoscopy as adenocarcinoma confined to the mucosa or submucosa irrespective of lymph node involvement [54]. The incidence of EGC remains extremely low outside South East Asia, as dedicated screening programs are not available. With tumors meeting certain endoscopic criteria, endoscopic resection is an option. Surgical resection still remains a commonly used approach for EGC and is associated with 5-year survival rate of up to 98% [40, 41]. If the expertise for EMR/ESD is not available, limited surgery with wide local resection is an option in suitable cases.

For tumors limited to mucosa, lymph node involvement rate is very low and is ≤3%, whereas the risk of nodal metastasis is 15–20% when the submucosa is involved. Thus, local resections can be offered in diseases confined to mucosa and a radical gastrectomy with lymphadenectomy is performed for diseases involving submucosa [55]. The role of sentinel lymph node mapping in EGCs is still considered investigational [56].

Laparoscopic radical gastrectomy (particularly distal subtotal resections) for relatively early stage gastric cancer offers short-term benefits in terms of reduced blood loss, pain and hospital stay in the postoperative period and is oncologically equivalent to open approach [57–59].

7.4 Role of Bursectomy During Radical Gastrectomy

Until recently, the role of routine bursectomy was debatable during gastric resections for cancer. Bursectomy has been recommended selectively by the Japanese guidelines for T4 or serosa involving tumors only as routine use may be harmful by causing pancreatic or vascular injuries during dissection. In 2014, a meta-analysis including two RCTs and three retrospective studies could not find any survival advantage with bursectomy as compared to nonbursectomy [60]. Patients with disease involving serosa showed a trend toward an improved OS with bursectomy; although the difference was not statistically significant. In 2018, a large RCT (JCOG1001) from Japan included over 1200 patients. The aim was to evaluate the benefit of bursectomy in gastric cancer. Nearly 80% of the included patients had cT3/T4a disease, and about 70% were node positive. The long-term results showed comparable 5-year OS rate (76%) in the bursectomy and nonbursectomy arm. Although bursectomy was safe, the authors did not recommend it routinely for cT3 or cT4a GC [61].

7.5 Lymphadenectomy During Radical Gastrectomy

The Japanese Gastric Cancer Association (JGCA) classifies the lymph node stations as well as the extent of lymph node dissection performed for gastric cancer. The extent of lymph node dissection is classified as D1, D2, D3 and D4 [51, 62]. D1 comprises dissection of station 1–6, D2 involves removal of D1 along with station 7–11 (Fig. 4), D3 takes in removal of D2 with station 12–14 (Fig. 5) and D4 means dissection of D3 with station 15–16.

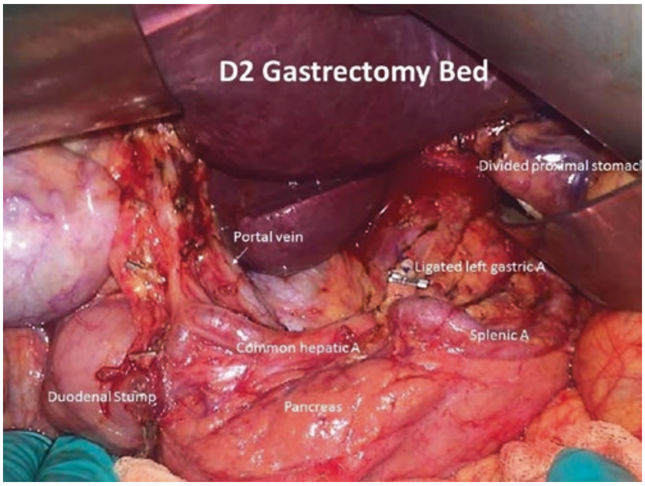

Fig. 4 Intraoperative image, post D2 lymph node dissection

D2 lymphadenectomy remains a standard practice in Japan since the 1960s. However, because of lack of survival benefit and higher postoperative morbidity shown in the initial results of the Dutch trial, D2 dissection did not gain popularity in the western world [63, 64]. A retrospective study from Tata Memorial Hospital suggests that morbidity and mortality following D2 lymphadenectomy (spleen preserving) is low, i.e., 8.8% and 1.25% [65].

A randomized controlled trial from Taiwan showed an overall survival (OS) and recurrence-free survival (RFS) benefit for a D2/D3 dissection as compared with D1 lymphadenectomy, without any added perioperative mortality [66].

Later, the 15-year follow-up of the Dutch Trial showed gastric cancer-specific deaths were less in the patients undergoing D2 dissection and the difference was statistically significant [67]. When the perioperative mortalities were excluded, the benefit of D2 was further amplified. As per the protocol of the trial, the standard D2 dissection at that time included routine performance of distal pancreaticosplenectomy which could have been the reason for higher perioperative morbidity/mortality with D2 surgery. With these results, the authors concluded and recommended spleen/pancreas preserving D2 dissection as a standard of care for patients with resectable gastric cancer.

In 2013, a meta-analysis that included 12 RCTs on various lymphadenectomies performed for gastric cancer resection did not find any survival benefit with D2 compared to D1 lymphadenectomy. But, similar to the long-term follow-up data of the Dutch trial, a subgroup analysis of patients undergoing spleen/pancreas preserving D2 dissection showed a trend for improved OS [68]. Additionally, the RFS was significantly better with D2 dissection. Only one trial in the meta-analysis evaluated D3 dissection and did not find any benefit as compared to D2 dissection.

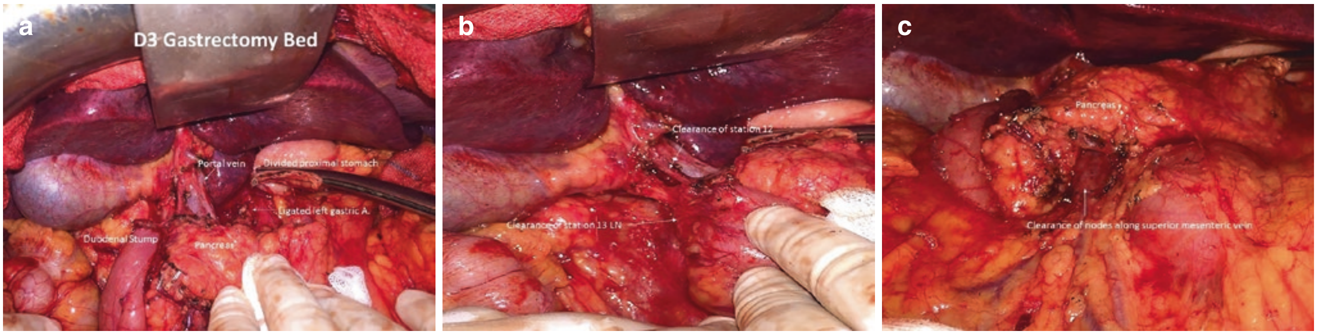

Fig. 5 (a–c) Intraoperative image, post D3 lymph node dissection

An ongoing “Phase III Randomized Trial Comparing D2 vs. D3 Lymphadenectomy with Gastric Cancer Following Neoadjuvant Chemotherapy” (ELANCe trial, clinicaltrials.gov trial ID—NCT02139605) is evaluating the role of D3 dissection for resectable gastric cancer after neoadjuvant chemotherapy [69].

To summarize, the present surgical standard of care remains a spleen preserving D2 dissection for all resectable gastric cancers excluding few early gastric cancers where lesser resection is possible. Distal pancreaticosplenectomy is no longer recommended as a routine practice with D2 dissection. At present a minimum of 16 nodes should be evaluated at histological examination to qualify for an adequate D2 dissection. Laparoscopic surgery is possible and has shown oncologically equivalent results when performed in high volume centers.

8 Medical Management

8.1 General Principles

The management of gastric cancer from a medical oncologist perspective depends on the stage of the primary disease as well as the institutional treatment protocol. All stages of gastric cancer beyond stage 1A tumors require an assessment by the medical oncology unit. For patients with Tis or T1, N0 disease who have uninvolved resection margins, observation is recommended. Adjuvant therapy is recommended for all patients with lymph node-positive disease, regardless of T stage.

The management and survival outcomes of LA-GC (T3/T4 N+ disease) have been markedly improved with the introduction of perioperative therapy. Based on multiple well-conducted Phase III trials, perioperative therapy is the present standard of care for patients with LA-GC. However, due to global variations in presentation and the differences in treatment strategies between the “West” (US, Western Europe) and “East”(Japan, South Korea, China), the standardized approach is yet to be defined. Recommended approaches to the treatment of LA-GC include perioperative chemotherapy and adjuvant therapy.

8.2 Perioperative Chemotherapy

The combination of neoadjuvant therapy, followed by radical surgery and adjuvant chemotherapy is primarily used in European countries and is practiced as per the results of the pivotal MAGIC trial as well as a later FNCLCC/FFCD study (albeit, having only 25% GC patients and analyzed early as a result of accrual issues) [43, 70]. The benefits of using neoadjuvant chemotherapy include tumor downstaging and thus improving R0 resections, micrometastases elimination, improving symptoms (tumor-related) and an assessment of tumor biology. While the MAGIC trial used the Epirubicin–5 Fluorouracil–Cisplatin (ECF), the French study used Cisplatin–5 Fluorouracil (CF) as their regimen of choice. Although there were some differences in the populations selected for the two trials in terms of baseline clinical characteristics, the benefits of perioperative chemotherapy in both trials were of a similar nature, being 13% and 14% (5-year mOS benefit) over surgery alone, respectively. Though ECF/CF have been shown effective in Phase III clinical trials, the ECF regimen used in the MAGIC trial was an infusional protocol requiring a central line (9 weeks over 3 cycles) which may not be feasible across clinical practice settings. As an alternative to this regimen, Epirubicin–Oxaliplatin–Capecitabine (EOX),, Epirubicin–Oxaliplatin–5 Fluorouracil (EOF) and Epirubicin–Cisplatin–Capecitabine (ECX) are acceptable regimens that can be used as neoadjuvant therapy. This is based on the near equivalence of these regimens in the locally advanced/metastatic setting and extrapolation of data to the perioperative setting. A large retrospective study from TMH has shown the feasibility of using EOX regimen as perioperative therapy in GC with outcomes on par with published data [71]. The benefit of a third drug, Epirubicin, over a cisplatin-5-Fluorouracil regimen of neoadjuvant chemotherapy was explored in the UK MRC OEO5 trial, which compared ECX with CF in locally advanced esophageal adenocarcinomas. While some benefit was observed in disease-free survival (DFS) and tumor regression, there was no benefit in OS, throwing into question the potential additional benefit of Epirubicin in the perioperative setting [72]. Further evidence of lack of benefit of an epirubicin-based regimen comes from the FLOT4-AIO trial, which evaluated perioperative chemotherapy with docetaxel, oxaliplatin and fluorouracil/leucovorin (FLOT) versus ECF/ECX for resectable gastric or gastroesophageal junction (GEJ) adenocarcinomas. There was clinically and statistically significant improvement in median PFS (18 months with ECX/ECF vs. 30 months with FLOT; p = 0.004) as well as median OS (35 months with ECX/ECF vs. 50 months with FLOT; p = 0.012) with the FLOT arm, thereby suggesting that FLOT should be current standard of care as perioperative therapy [73].

8.3 Adjuvant Therapy

Upfront surgery followed by adjuvant chemotherapy is the current standard practice in centers from South East Asia treating gastric cancers in high volumes. This standard has been established based on well conducted Phase III trials, including older trials like INT-116 and newer studies such as

ACTS-GC, CLASSIC and ARTIST, which examined the role of adjuvant therapy after a D2 Gastric resection [44, 45, 47, 48]. There have been at least four meta-analyses of adjuvant therapy trials which have confirmed survival benefit of adjuvant therapy as against surgery alone in this subset of patients, and hence, adjuvant therapy is the current standard in patients undergoing upfront D2 Gastric resections [46, 74, 75]. While "adjuvant therapy" is standard, there exists some debate over chemotherapy alone vs. chemoradiation as the appropriate adjuvant therapy. Beyond INT-116, which essentially had a small proportion of D2 resections (approximately 10%), high incidences of acute toxicity as well as outdated radiotherapy techniques and no chemotherapy-only arm, the study in the current era which was best positioned to answer this debate was the well planned ARTIST trial [44, 45]. The updated analysis after a median 7-year follow-up comparing chemotherapy (Capecitabine–Cisplatin for alone cycles) vs. chemoradiation (Capecitabine–Cisplatin for two cycles, followed by chemoradiotherapy and further Capecitabine–Cisplatin for two cycles), in an intention to treat analysis, showed no difference between the arms in terms of median DFS or median OS. However, an unplanned subset analysis suggested OS benefit in patients with diffuse type GC and node-positive disease. Additional caveats regarding the role of chemotherapy alone vs. chemoradiation are elucidated in two large meta-analyses evaluating the two modalities, which showed an improvement with chemoradiation in DFS and loco regional recurrence-free survival, but no improvement in OS [76, 77]. In areas where expertise for D2 resections does not exist, chemoradiation can be considered as adjuvant therapy as opposed to chemotherapy alone.

9 Radiotherapy

9.1 Neoadjuvant Chemoradiation

The remarkable improvement in outcomes seen with neoadjuvant chemoradiation and surgery vs. surgery alone in resectable esophageal cancers has not been translated into routine use in gastric cancers [78, 79]. While there is a well-designed phase II/III trial (TOPGEAR) evaluating such an approach in esophagogastric and gastric adenocarcinomas ongoing, such an approach should only be considered within a trial setting [80].

9.2 Adjuvant Chemoradiation

The combination of improved surgical techniques, greater emphasis on D2 gastric resections as standard as well as improvement in systemic chemotherapy have lessened the role of adjuvant chemoradiation in R0 resected gastric cancers, though controversy still exists on certain aspects. While the seminal INT116 study was the first study which showed improved outcomes with adjuvant chemoradiation, more recent data has raised questions on the benefit of adjuvant chemoradiation as opposed to adjuvant chemotherapy alone [44, 81]. Certain aspects of this contentious issue have been covered previously.

Beyond the previously discussed ARTIST study in which patients who underwent upfront surgery were randomized, another aspect of adjuvant therapy is the role of adjuvant chemoradiation after surgery following neoadjuvant chemotherapy. This precise question was evaluated by the phase III RCT (CRITICS trial), which evaluated patients with stage Ib–IVa resectable gastric cancer. Both arms received neoadjuvant chemotherapy with 3 courses of ECX or EOX. Post radical gastrectomy, adjuvant therapy was either 3 courses of ECX/EOX or concurrent chemoradiation (45 Gy in 25 fractions combined with weekly cisplatin and daily capecitabine) [82]. The 5-year OS was not different between both arms (41.3% vs. 40.9%; $p = 0.99$). However, in R1 resections, there appears to be a benefit for adjuvant chemoradiation as compared to observation alone, though observation would not be considered standard in resected gastric cancers beyond stage IB in the current era [83].

9.3 Radiotherapy Protocol

The minimum standard that should be employed in the adjuvant potentially curative setting should be three dimensional CT-based planning. The target volume should include the primary tumor or resection bed, gastric remnant (after partial or subtotal gastrectomy) and regional lymph nodes. The inclusion of surgical anastomosis or the divided first part of duodenum may be considered in certain settings. The standard dose in the adjuvant setting includes 45 Gy given in 25 daily fractions. In case of a gross residual disease or for a positive surgical margin, a boost of 5.4–9 Gy may be given [84].

10 Medical Management of Advanced Inoperable/Metastatic Gastric Cancers

The treatment of AGC comprises of continued supportive care as well as chemotherapy and rarely, radiotherapy and surgery. While these patients are treated with "palliative" noncurative intent, it is incumbent on the treating physician to ensure maximum symptom palliative as well as appropriate systemic chemotherapy. A certain proportion of patients will probably benefit maximally from supportive care only.

Patients on palliative chemotherapy for advanced gastric cancers also benefit from referral for early palliative care as an ongoing process [85].

The chemotherapeutic basis for the management of AGC revolves around a 5 Fluorouracil/Platinum doublet, with varying modifications of this combination as well as addition of a third agent, i.e., docetaxel and epirubicin, improving response rates and potentially, survival.

Based on the REAL study and ML17032 studies, an Epirubicin–5 Fluorouracil/Capecitabine-Cisplatin/Oxaliplatin triplet is a regimen of choice in patients with overall good general condition (good ECOG/PS) and possibility of timely visits in the clinic to assess toxicity [86]. A Docetaxel–Cisplatin–5 Fluorouracil (DCF) triplet combination is also associated with good response rates and mOS, although with high rate of Grade 3 and Grade 4 toxicity. An mDCF regimen (with reduced Docetaxel and cisplatin doses) has been associated with improved survival and tolerability as compared to the classical DCF regimen [87]. A variation of this triplet is the Docetaxel–Oxaliplatin–Capecitabine combination, which is widely used and builds upon the marginally better outcomes associated with Capecitabine when compared to 5 Fluorouracil and Oxaliplatin [88, 89].

When triplet combination is not feasible, a doublet Cisplatin/Oxaliplatin–5 FU/Capecitabine is an acceptable regimen. Despite the superior response rates and marginally improved survival associated with a triplet, a well conducted Phase III French trial actually showed no difference in median PFS and OS between FOLFIRI (5 Fluorouracil–Irinotecan) and ECX (Epirubicin/Cisplatin/Capecitabine) [90].

As opposed to combination regimens, single-agent Docetaxel, Paclitaxel and Capecitabine have also shown feasibility and can be used as palliative chemotherapy.

While chemotherapy remains the backbone of therapy for AGC, HER2-neu-positive AGC has the additional option of adding Trastuzumab to a 5 FU–Platinum doublet as per the results of the TOGA trial [91]. No other anti-HER2 neu-directed therapy has shown benefit over conventional chemotherapy. The use of other targeted agents such as bevacizumab and ramucirumab has not shown statistical or clinically significant benefits in combination chemotherapy as opposed to chemotherapy alone in the first-line therapy [92–94].

In patients with progression or recurrence after initial first-line therapy, but with adequate organ function and ECOG PS, recommended second-line agents include Paclitaxel, Docetaxel, Irinotecan and Ramucirumab (as monotherapy or in combination with paclitaxel) [95–97]. All these agents have proven modest but statistically significant survival benefit over best supportive care only with improvement in QOL as well. FOLFIRI combination chemotherapy can also be considered as an appropriate second-line regimen in fit patients [98]. While the above mentioned drugs are recommended in the second-line settings, a review of the cost benefit ratio as well as expectedly modest benefits should be discussed while planning therapy for individual patients [99].

10.1 Immunotherapy

The approval of pembrolizumab in patients with tumors showing microsatellite instability (MSI-H) is a first for any kind of therapy in terms of being a tumor agnostic marker [100]. Pembrolizumab and nivolumab have both been evaluated in advanced gastric cancers post two lines of therapy with modest benefits, making them feasible options in such a setting [101, 102].

11 Stage-Wise Survival of Gastric Cancer

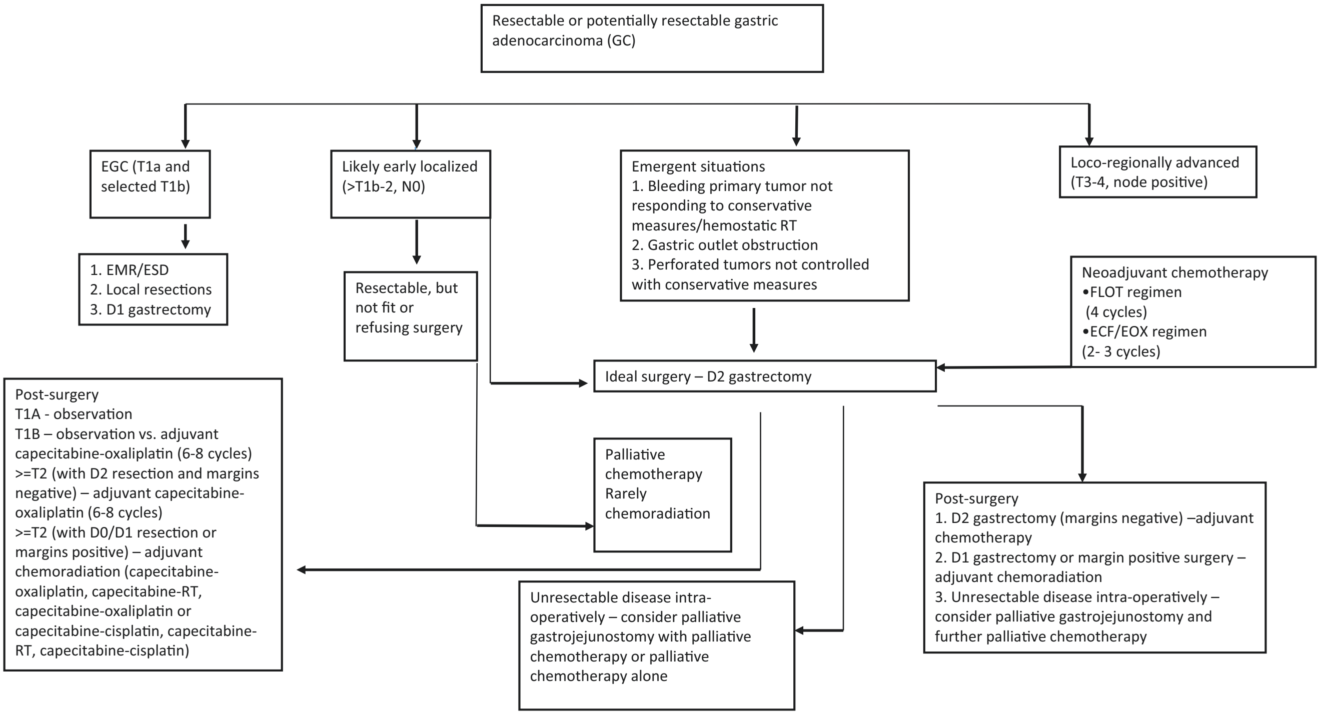
The last two decades have witnessed an improvement in survival for patients with gastric cancer; across stages, based on a combination of improved surgical techniques, systemic chemotherapy, the advent of targeted therapy as well as better supportive care. Such an improvement has been noted in trials as well as in population-based data. However, there is a vast disparity in survival across population, the premier example of which is the improved difference in survival seen across stages in patients treated in South East Asia as opposed to Europe and North America. The improved survivals seen in south-east Asia has been considered related to screening programs, possible earlier diagnosis, different pathological staging, different biology and differential expertise and uptake of D2 resections [103–105]. Based on available data from the National Cancer Database survival data, a rough guide to expected 5-year survival as per stage is presented in Table 2 with data for stage IV cancers as per available trial data [106].

Table 2 Stage-wise survival for gastric cancer

Stage	5-year overall survival (%)
I	88–94
II	68–82
III	18–54
IV	5–15

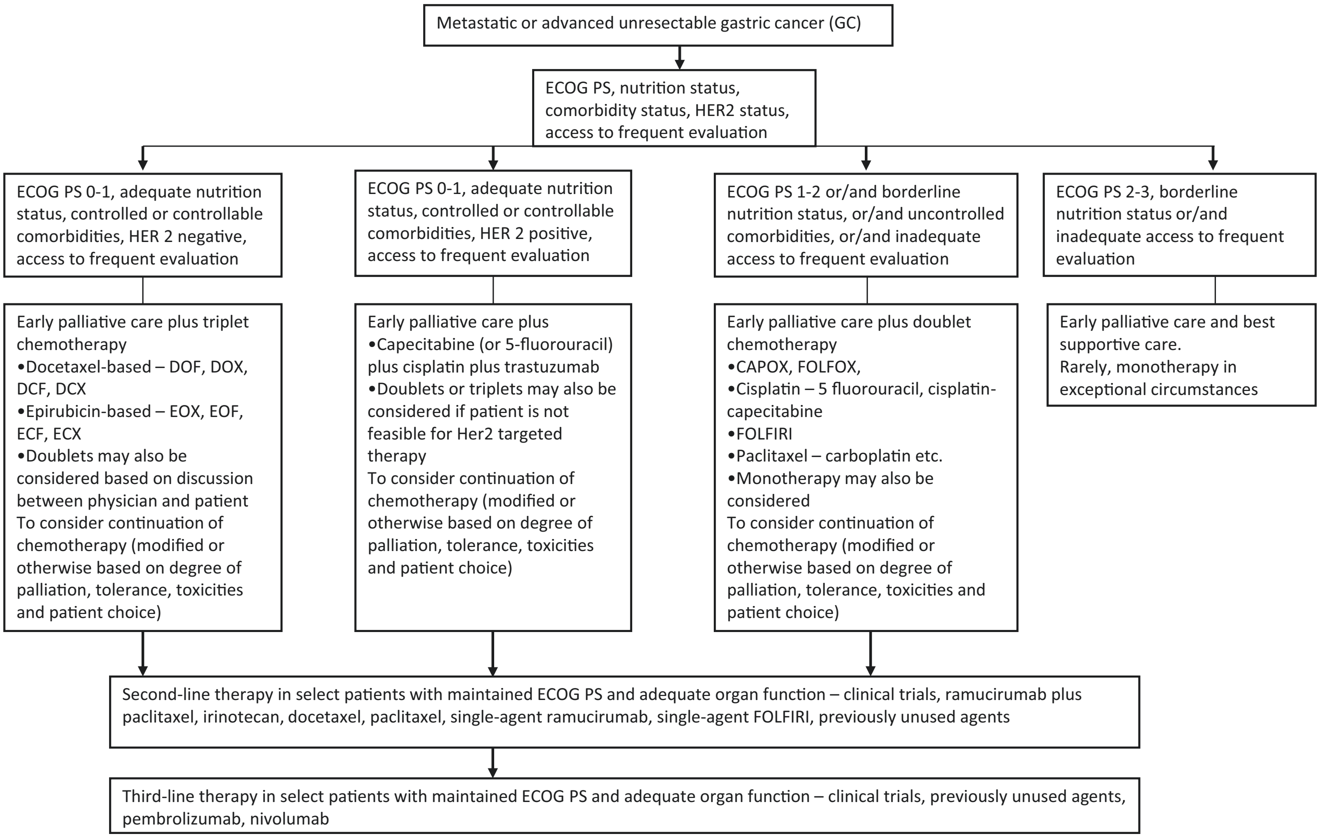
12 How We Do It at TMC

Figures 6 and 7 present suggested treatment algorithms based on the multidisciplinary approach used in Tata Memorial Hospital.



Resectable or potentially resectable gastric adenocarcinoma (GC)
EGC (T1a and selected T1b)
1. EMR/ESD
2. Local resections
3. D1 gastrectomy
Likely early localized (>T1b-2, N0)
Resectable, but not fit or refusing surgery
Emergent situations
1. Bleeding primary tumor not responding to conservative measures/hemostatic RT
2. Gastric outlet obstruction
3. Perforated tumors not controlled with conservative measures
Loco-regionally advanced (T3-4, node positive)
Neoadjuvant chemotherapy
•FLOT regimen (4 cycles)
•ECF/EOX regimen (2- 3 cycles)
Ideal surgery – D2 gastrectomy
Post-surgery
T1A - observation
T1B – observation vs. adjuvant capecitabine-oxaliplatin (6-8 cycles)
>=T2 (with D2 resection and margins negative) – adjuvant capecitabine-oxaliplatin (6-8 cycles)
>=T2 (with D0/D1 resection or margins positive) – adjuvant chemoradiation (capecitabine-oxaliplatin, capecitabine-RT, capecitabine-oxaliplatin or capecitabine-cisplatin, capecitabine-RT, capecitabine-cisplatin)
Palliative chemotherapy Rarely chemoradiation
Unresectable disease intra-operatively – consider palliative gastrojejunostomy with palliative chemotherapy or palliative chemotherapy alone
Post-surgery
1. D2 gastrectomy (margins negative) –adjuvant chemotherapy
2. D1 gastrectomy or margin positive surgery – adjuvant chemoradiation
3. Unresectable disease intra-operatively – consider palliative gastrojejunostomy and further palliative chemotherapy

Fig. 6 Treatment algorithm for localized/resectable GC



Metastatic or advanced unresectable gastric cancer (GC)

ECOG PS, nutrition status, comorbidity status, HER2 status, access to frequent evaluation

ECOG PS 0-1, adequate nutrition status, controlled or controllable comorbidities, HER 2 negative, access to frequent evaluation

Early palliative care plus triplet chemotherapy
•Docetaxel-based – DOF, DOX, DCF, DCX
•Epirubicin-based – EOX, EOF, ECF, ECX
•Doublets may also be considered based on discussion between physician and patient
To consider continuation of chemotherapy (modified or otherwise based on degree of palliation, tolerance, toxicities and patient choice)

ECOG PS 0-1, adequate nutrition status, controlled or controllable comorbidities, HER 2 positive, access to frequent evaluation

Early palliative care plus
•Capecitabine (or 5-fluorouracil) plus cisplatin plus trastuzumab
•Doublets or triplets may also be considered if patient is not feasible for Her2 targeted therapy
To consider continuation of chemotherapy (modified or otherwise based on degree of palliation, tolerance, toxicities and patient choice)

ECOG PS 1-2 or/and borderline nutrition status, or/and uncontrolled comorbidities, or/and inadequate access to frequent evaluation

Early palliative care plus doublet chemotherapy
•CAPOX, FOLFOX,
•Cisplatin – 5 fluorouracil, cisplatin-capecitabine
•FOLFIRI
•Paclitaxel – carboplatin etc.
•Monotherapy may also be considered
To consider continuation of chemotherapy (modified or otherwise based on degree of palliation, tolerance, toxicities and patient choice)

ECOG PS 2-3, borderline nutrition status or/and inadequate access to frequent evaluation

Early palliative care and best supportive care.
Rarely, monotherapy in exceptional circumstances

Second-line therapy in select patients with maintained ECOG PS and adequate organ function – clinical trials, ramucirumab plus paclitaxel, irinotecan, docetaxel, paclitaxel, single-agent ramucirumab, single-agent FOLFIRI, previously unused agents

Third-line therapy in select patients with maintained ECOG PS and adequate organ function – clinical trials, previously unused agents, pembrolizumab, nivolumab

Abbreviations

CEA	Carcinoembryonic antigen
CECT	Contrast-enhanced computed tomography
CHRPE	Congenital hypertrophic retinal pigment epithelium
CME	Complete mesocolic excision
COST	Clinical Outcomes of Surgical Therapy Study Group
CRC	Colorectal cancer
CRM	Circumferential radial margin
CRS	Cytoreductive surgery
CTC	CT colonography
DCBE	Double-contrast barium enema
EGFR	Epidermal growth factor receptor
EMR	Endoscopic mucosal resection
ESD	Endoscopic submucosal dissection
FAP	Familial adenomatous polyposis
FIT	Fecal immunochemical test
FOBT	Fecal occult blood test
HDI	Human development index
HIPEC	Heated intraperitoneal chemotherapy
HNPCC	Hereditary nonpolyposis colorectal cancer
LR	Local recurrence
MOSAIC	Multicenter International Study of Oxaliplatin/5-FU/Leucovorin in the Adjuvant Treatment of Colon Cancer Trial
NBI	Narrow-band imaging
OS	Overall survival
QOL	Quality of life
RR	Recurrence rate
TME	Total mesorectal excision
TPA	Tissue polypeptide antigen
TPS	Tissue polypeptide-specific antigen
VEGF	Vascular endothelial growth factor

1 Introduction

Colorectal cancer is one of the most common cancers encountered in clinical practice worldwide. Over 1.8 million new colorectal cancer cases and 881,000 deaths are estimated to occur in 2018, and it ranks third in terms of incidence but second in terms of mortality. It is the third most common cancer in men and second in women [1] Traditionally, colorectal cancer has been recognized as a malignancy of the developed world with the highest incidence rates reported in parts of Europe, Australia, New Zealand, North America, and East Asia and the lowest rates in Africa and Southern Asia. However, recent statistics suggest a declining trend in the developed world which has been attributed largely to the adoption of best practices in cancer

treatment including screening and efforts directed towards early detection [1]. On the other hand, with increasing urbanization, economic development, growing westernization, and an increasing human development index (HDI), a sharp increase in the incidence has been noted in the developing world [1]. Surgery forms the mainstay in the curative treatment of colon cancer. However, modern polyagent chemotherapy, targeted therapy, and the newly introduced immunotherapy significantly improve survival outcomes in the advanced and metastatic stages of the disease. This chapter deals with colon cancer, its pathogenesis, prognosis, and current standards of care.

2 Incidence and Epidemiology in India and the World

2.1 Incidence

The incidence of colorectal cancer (CRC) demonstrates significant geographic variation. In India, colon cancer ranks ninth among the most common cancers in men and women vis-à-vis the western world where it constitutes the third most common cancer in men and the second most common in women [1].

2.2 World Trends

For both sexes combined, lung cancer is the most commonly diagnosed cancer (11.6% of all cases) and the leading cause of cancer deaths (18.4% of all cancer deaths) closely followed by female breast cancer (11.6%) and colorectal cancer (10.2%). Overall, colorectal cancer ranks third in terms of incidence but second in terms of mortality [1] The annual age-standardized incidence rate in the United States for colorectal cancer from 2009 through 2013, was 40.7 per 100,000 persons with a mortality rate of 14.8 per 100,000 persons [2] Although incidence and mortality rates are higher in men than women, the lifetime risk of the disease is similar owing to the longer female life expectancy. The socioeconomic disparity in the incidence of colorectal cancer is attributed to an unequal prevalence of risk factors such as obesity, unhealthy diet, and smoking [3].

2.3 Domestic Trends

There is very little variation in the incidence rates of CRC across India, unlike the striking regional differences in the incidence rates of stomach and gall bladder cancer. Population-based time-trend studies show a rising trend in the incidence of CRC in India. Indian immigrants to the United Kingdom and the USA have higher incidence rates of CRC as compared to their Indian counterparts, suggesting that lifestyles and dietary habits probably have some causative influence. This also suggests that as India transitions from a low to a middle-income economy, there will be a substantial increase in the burden of colorectal cancer [4] The absolute burden of CRC has also increased in India during the last three decades. During a 32-year period (1941–1972), 555 cases of CRC were recorded at the Tata Memorial Hospital, Mumbai [5]. In contrast, a total of 560 cases of CRC were treated at the same institution in 2006 alone. Age-adjusted colon cancer incidence rates for the world standard population per 100,000 persons in India are 4.3 for males and 3.4 for females [4].

Colorectal cancer in India tends to present at a younger age, at a more advanced stage, with a higher incidence of signet-ring morphology, and more likely to arise in the anorectum vis-à-vis colon [6–11] A study conducted at the Tata memorial hospital, Mumbai confirmed the above findings where the mean age of patients presenting with a colorectal primary was 47.2 years with 35% of them aged below 40 and 80% below 60 years [6] This is in contrast to Western literature, especially in the United States, where 90% of new CRC cases are above 50 years at diagnosis and 58% of all new CRC cases are above 65 years of age [12]. Whether the increased incidence of CRC at a younger age is due to a larger proportion of young people in the population pyramid as compared to the West (which has a significant proportion of aging individuals) or whether it truly reflects an actual difference in the age at presentation is not certain. Additionally, the available Indian data originates from isolated centres in the country which may be influenced by a referral bias and not entirely indicative of the disease presentation in the general population.

3 Etiology and Risk Factors

Colorectal cancers occur in three principal forms—sporadic, familial, and hereditary. About 2–5% of colorectal cancer cases occur in the setting of defined inherited syndromes like Lynch, Familial Adenomatous polyposis, MUTYH polyposis, etc. These constitute the hereditary group. Roughly one-third of incident cases show strong familial clustering, i.e., the Familial group. These families demonstrate a number of inheritable genetic mutations with variable penetrance. Gene polymorphisms, gene modifiers, and tyrosine kinase defects are the possible inciting factors along with associated environmental influences. Acquired and genetic anomalies like the c-myc gene amplification, ras point mutations, p53 mutations, and chromosome 5, 17, 18q allelic deletions have been recognized as causative factors in carcinogenesis. Though family history accounts for the highest relative risk amongst the etiologic factors for colorectal cancer, sporadic cases are by far the largest group seen in clinical practice.

The etiopathogenesis of colorectal cancer is one of the most extensively studied entities in cancer pathology. Factors implicated in colorectal cancer pathogenesis include:

1. Distribution, nationality, race, and religion—Colorectal cancer, as mentioned, is a disease predominantly of the Western populace with factors like lifestyle, dietary habits, and rapid industrialization being implicated in its etiopathogenesis. Low-risk populations seem to have a relatively increased incidence of right-sided cancers, whereas high-risk communities have an increased risk of left-sided malignancies [13–15]. Jews have a higher incidence than any other religious community [16–19].
2. Age—The likelihood of an individual developing colon cancer increases progressively after the age of 40 with a sharp rise after 50. Incidence rates are more than 50 times higher in the seventh and eighth decades of life than in those younger than 40 years. Recent trends however show an increasing incidence among the younger population [20].
3. Dietary factors—Low-residue, high-carbohydrate diet has been shown to have a contributory role in colorectal carcinogenesis [21] Dietary fiber exerts a protective influence probably due to the abundance of inositol hexaphosphate in plant fiber which acts as a specific anti-cancer agent [22]. Another hypothesis to explain the protective influence of dietary fiber is the increase in stool bulk and dilution of putative carcinogens in the colonic lumen by more rapid transit with diminished mucosal exposure to injurious agents [23].

   High intake of animal fat and protein has been demonstrated to have a strong correlation by some investigators. Populations with high beef consumption are known to have the highest incidence of bowel cancer [24] However, this association has been controversial since other investigators have only found a weak association between CRC and the consumption of red meat or saturated fat [25].
4. Polyps—Precursor lesions found in the colon like tubular and villous adenomatous polyps are a known risk factor for developing malignancy over time. A majority of the sporadic colon cancers develop from these adenomatous polyps albeit with a long latency period of 5–10 years [26].
5. Inflammatory bowel disease—Ulcerative colitis and Crohn's disease are known risk factors for colorectal cancer. The extent of colonic involvement and the duration of colitis are directly proportional to the extent of cancer risk.
6. Fecal bile acids—High concentrations of fecal secondary bile acids like deoxycholic and lithocholic acid, typically seen in the Western diet have been confirmed by population-based studies in patients with colon cancer [27, 28]. An unambiguous relation between the fecal bile acid level and the incidence of dimethlyhydrazine-induced colon cancer has been established [29]. Hence, cholecystectomy has also been implicated as a possible precipitating factor by increasing the enterohepatic circulation of secondary bile acids [30, 31].
7. Familial colon cancer—Up to 20% of the CRC afflicted have a familial history of colorectal cancer or adenomatous polyps in one or more first-degree relatives. The risk increases with the number of relatives affected and their age at diagnosis, possibly due either to inherited genes combined with the influence of shared environmental factors [32].
8. Genetic factors—About 5 to 10% of colorectal cancers stem from recognized hereditary conditions like familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC).FAP is associated with a mutated tumor suppressor gene *APC* while HNPCC is associated with gene mutations of the DNA mismatch repair pathway i.e.*MLH1*&*MSH2* among others. Other genetic syndromes like the Peutz-Jeghers syndrome, Familial juvenile polyposis, and MUTYH-associated polyposis are also associated with increased colorectal cancer risk.

4 Clinical Presentation in India and the World

The clinical presentation of colon cancer may vary from minor but persistent changes in bowel habits to surgical emergencies like obstruction or bowel perforation. Primary symptoms, i.e., attributable to the colonic primary, include a change in bowel habits (commonest), bleeding, and abdominal pain. Distal large bowel lesions are more prone to be symptomatic than more proximal lesions. Bleeding is the second most common symptom which could be occult or overt. Chronic anemia secondary to occult intraluminal tumor bleed, often requiring blood transfusions, is a common presentation of right colon cancer. Bleeding left colon and rectal lesions tends to be overt with less alteration in the character of the blood which appears brighter. Passage of mucus either mixed with stool or blood is highly suggestive of neoplastic etiology and necessitates a complete evaluation. Abdominal pain is usually due to luminal bowel obstruction (either partial or complete), is colicky in nature, and could be associated with other symptoms like nausea, vomiting, or abdominal distension. Back pain due to retroperitoneal infiltration is a late sign. Rarely a palpable abdominal mass can be the only presenting symptom.

Systemic symptoms like significant unintentional weight loss, anorexia, fatigue, cutaneous manifestation (acanthosis nigricans, dermatomyositis, and pemphigoid), and symptoms suggestive of anemia, are all pointers towards a neoplastic colorectal etiology. A palpable left supraclavicular node (Virchow node, Toisier sign), palpably enlarged liver, jaundice (due to extensive liver parenchymal metastasis or biliary obstruction due to metastatic portal nodes), ascites, and rarely bone pain (due to bone metastasis usually in the vertebra and pelvic bones) constitute symptoms and signs of metastatic disease.

Perforation peritonitis, appendicitis due to a caecal tumor obstructing the appendiceal lumen, a perforated caecum due to an obstructing carcinoma of the distal large bowel (due to closed loop obstruction), and incarcerated hernia especially in the elderly are uncommon presentations of colonic malignancy.

5 Evaluation and Work-Up

5.1 Screening

Survival in colorectal cancer, like other gastrointestinal tumors, is a function of the stage at initial disease presentation. Colorectal cancer is largely sporadic, arising from premalignant adenomas that acquire serial genetic mutations to finally transform into the malignant phenotype, over 8–10 years [33]. This asymptomatic, pre-malignant phase provides an opportunity for screening in average-risk individuals (i.e., individuals aged 50-75 yrs. without a personal or family history of colorectal carcinoma or polyps) to detect and resect colorectal adenomas before they become malignant. A population-based screening program is only cost-effective if the disease in question is a public health problem (i.e., high incidence). The incidence of colorectal cancer in India may not at this time, warrant a nationwide population-based screening program. However, it should be noted that a large percentage of colorectal cancer cases presenting at tertiary centers are individuals <40 years old and in advanced stages of the disease [6]. Many of these individuals are treated at the village and district level for benign anorectal conditions (hemorrhoids, anal fissure, etc.) for a long period of time before being finally diagnosed as colorectal carcinoma. Perhaps adopting a 'symptom-based pathway' i.e. sigmoidoscopy/colonoscopy for symptomatic individuals (chronic lower gastrointestinal symptoms, benign anorectal disease) irrespective of age may aid in diagnosing cancer in these individuals at an earlier stage.

The majority of international guidelines, recommend screening for colorectal cancer by one of three options viz. fecal occult blood test (FOBT, mainly the fecal immunochemical test (FIT), annually or biennially), flexible sigmoidoscopy every 5 years or colonoscopy every 10 years [34].

Fecal occult blood testing (FOBT) is the only screening modality supported by evidence from prospective randomized trials. FOBT on two samples from each of three consecutive stools followed by colonoscopy if positive, has demonstrated a survival benefit (mortality reduction of 15–33%) [35]. AnnualFOBT together with a 5-yearly flexible sigmoidoscopy has been found to be superior to either modality alone. The older guaiac-based FOBT detects the presence of blood in feces through the peroxidase activity of heme. The results of this test could therefore be confounded by the presence of dietary peroxidases such as heme from the myoglobin of red meat, plant peroxidases, and even antioxidants like Vitamin C. Additionally, the test has low sensitivity for both CRC (25–38%) and advanced adenomas (16–31%) [36]. The FIT is a newer version of the guaiac FOBT with an antibody to human globin protein without any cross-reactivity to animal-derived protein. Therefore, no dietary restrictions are needed before testing. Another advantage is the specificity for colonic blood since upper GI globin is degraded by proteolytic enzymes. The FIT is, therefore, a simpler test, requiring fewer samples and with greater sensitivity for advanced adenomas and CRC than the guaiac-ased test [37].

Double-contrast barium enema (DCBE) has, for all practical purposes been relegated in today's times to the pages of history. Better investigative procedures like colonoscopy and computed tomography have virtually replaced DCBE. There are no studies to support a reduction in the incidence or mortality of CRC in average-risk individuals with DCBE [38]. The need for a subsequent colonoscopy should there be a positive finding on DCBE has made the procedure redundant. However, in the absence of expertise in colonoscopy, a 5-yearly screening with DCBE, from the age of 50 years could be employed as the next best alternative.

Flexible sigmoidoscopy has been recommended as a preferred initial tool for colorectal cancer screening [39], as the majority of colorectal cancers are in the left colon, within the reach of detection by the flexible sigmoidoscope. Additionally, complete bowel preparation is not required. A single phosphate enema is sufficient to clear the distal colon. Combining 5-yearly flexible sigmoidoscopy with annual FOBT significantly increases the yield of detection. All positive tests are followed up with a complete colonoscopy.

Colonoscopy has been universally accepted as the gold standard for colorectal cancer screening due to its sensitivity and specificity approaching 100% in experienced hands. Cancer-related mortality can be lowered by 68%–88% among individuals who undergo screening colonoscopy as compared to those who do not [40].Despite being a relatively safe procedure (risk of perforation <0.1%) that is readily available, colonoscopy does require full bowel preparation and sedation.

CT colonography (CTC) is a structural imaging test, developed in 1994where cross-sectional images of the abdomen and pelvis are obtained after insufflation of the large bowel with air or carbon dioxide. It is relatively less invasive than an optical colonoscopy, does not require anesthesia, and has an image acquisition time of about 15 seconds. Bowel preparation and rectal catheter insertion are however necessary for this technique. The CTC finds utility as a triage modality in individuals at low to medium risk for CRC subjecting patients to a complete colonoscopy only if a polypectomy is required [41].CTC could also serve as an alternative in patients who cannot undergo an optical colonoscopy due to the risk of associated complications, ongoing anticoagulation therapy, or the presence of significant co-morbidities. Overall sensitivity of over 90% for polyps >10 mm in size has been observed, although marked heterogeneity is noted among published reports [42, 43].

5.2 Work-Up

The minimum cancer staging directed work-up for a patient with suspected colon cancer would include

- Colonoscopy + biopsy.
- Imaging—Contrast-enhanced computed tomography (CECT) of the thorax, abdomen, and pelvis.
- Tumor markers—Carcinoembryonic antigen (CEA), CA19–9.

5.2.1 Colonoscopy

Optical colonoscopy is the accepted gold standard for the evaluation of colon cancer with three main advantages—complete and direct visualization of the entire colon and rectal mucosa, the ability to obtain a biopsy to establish tissue diagnosis, and the possibility of therapeutic intervention with the removal of precancerous lesions.

A complete colonoscopy is essential because there is a possibility of synchronous cancers (2–10%) or polyps (15–50%) [44–46]. With obstructing tumors, complete intubation of the colon may not be possible. In these situations, a complete colonoscopy is recommended within 6 months following definitive surgery.

High-definition, white-light, optical colonoscopy, which is the standard of care may be further enhanced with the following:

- Chromoendoscopy—An enhanced imaging technique in which contrast agents (e.g., indigo carmine) are applied locally to the mucosa during endoscopy to visualize mucosal abnormalities. The Kudo scoring system is utilized for polypoid lesions which is based on mucosal pit patterns. Improved visualization of early neoplastic lesions is a noted advantage of this technique.
- Magnification endoscopy—High-resolution magnified images for further characterization of neoplastic lesions.
- Narrow-band imaging (NBI)—The oldest established method of virtual chromoendoscopy. Conventional white light video endoscopy utilizes the entire visible spectrum while NBI is based on an integrated filter system that narrows the spectrum and accentuates the blue light spectrum thus providing a clearer contrast enhancement of the architecture of mucosal vessels.
- Intelligent color enhancement (FICE) (Fujinon) and iScan imaging (Pentax)—are processor-integrated software applications that alter the wavelength ranges of reflected light and thus offer a number of filter options to enhance mucosal lesion-detection rates.
- Autofluorescence endoscopy—Also known as the Red Flag technology, this technique is based on the concept of fluorescence produced by auto fluorophores or exogenously introduced fluorophores like 5-Aminolevulinic acid. It plays a significant role in the early detection of dysplasia.
- Endomicroscopy—The first endoscopic procedure that, in addition to the analysis of surface structure, permits microscopic analysis of cellular structures of the mucous membranes in vivo.

5.2.2 Imaging

A CECT of the thorax, abdomen, and pelvis is recommended for every patient with colon cancer. A pre-CECT confirmation of adequate renal function is mandatory before the use of intravenous (IV) contrast. Both an IV and oral contrast study is the recommended protocol. In patients in whom a CECT is contraindicated, an MRI of the abdomen and pelvis is the recommended alternative.

Colon cancer appears as enhancing mural thickening of the colonic wall. Early lesions appear as polyps (either sessile or pedunculated) while advanced cancers are usually seen as “saddle” or “apple core” lesions due to circumferential narrowing of the lumen, overhanging borders, and mucosal destruction. Every attempt should be made to determine the T, N, and M stage on baseline imaging (Table 1). The main advantage of a preoperative CECT of the thorax is that it is not only more sensitive than a conventional chest X-ray to pick up pulmonary metastasis but also provides a baseline scan for subsequent comparison should there arise a suspicion of metachronous pulmonary metastasis [47].

PET-CECT is not recommended for routine initial staging of patients with colon cancer, but may be useful in the following clinical situations:

- Evaluating the nature of indeterminate lesions detected on conventional imaging.
- A rising CEA in a patient on surveillance after completion of definitive treatment.
- In the setting of recurrent disease.

Table 1 Interpretation of a CECT for colon cancer

Establishing the T stage Enhancing mural wall thickening—likely site of primary colon cancer Pericolonic fat stranding i.e. at least T3 Frank infiltration of surrounding organs i.e.T4b—determine the feasibility of multi-visceral resection with negative margins, depending on the organs involved
Establishing the N stage Evaluate the presence of perilesional nodes, nodes along the draining vessels, and nodes along the root of the draining pedicles. Unresectable nodal disease at the root of the draining pedicle may render a patient inoperable
Establishing the M stage Evaluate for liver metastasis, nodes at the porta hepatis, non-regional (retroperitoneal) nodal metastasis, ascites, peritoneal disease, lung and bone metastasis
Look for the presence of potential surgical complications Tumour perforation (free intraperitoneal gas), intestinal obstruction (dilated bowel loops), closed-loop obstruction (left colon primary, dilated colon, collapsed small bowel)

- Detection of occult metastatic disease prior to embarking on major resections for metastatic disease.

5.2.3 Tumor Markers

Serum tumor markers(CEA and CA 19–9) are utilized in the detection, diagnosis, and treatment of patients of colon cancer.CEA finds its utility primarily as a prognostic marker after diagnosis and to monitor disease progression. Elevated CEA levels also portend a poor prognosis for resectable CRC [48]. Levels fall post tumor resection and the sensitivity is known to increase with the tumor stage [49]. The application of CEA as a screening tool is hindered by the fact that elevated levels are non-specific and can be found in benign conditions as well. Additionally, in a fraction of patients, CEA levels rise only in the advanced stages of the disease.

CA 19–9 antigen as a tumor marker is less sensitive and specific for CRC as compared to CEA. Tissue polypeptide-specific antigen (TPS) and tissue polypeptide antigen (TPA) are known to be elevated in metastatic CRC but are unsuited for screening due to low sensitivity and specificity. A combination of TPA and CEA has greater sensitivity in identifying recurrent diseases [50]. Other biomarkers of significance are circulating tumor cells, circulating DNA-based biomarkers like the cell-free DNA, its integrity and genetic alterations, microsatellite instability, detection of aberrant DNA methylation of the SEPT9 gene, RNA-based markers amongst others, with many still in the research stage.

5.3 Pathology

5.3.1 Gross Pathology

There are various patterns of growth morphology seen in colon cancer. Carcinomas of the proximal colon are for the majority, polypoid and exophytic often outgrowing their blood supply and subsequently undergoing necrosis. Tumors of the distal colon grow in a more circumferential manner with a 'napkin-ring' configuration. The fibrous stroma of the tumor is responsible for the constricting nature with resultant luminal compromise, whereas the annular or circumferential growth pattern occurs due to the circular arrangement of lymphatics along the colon wall. The clinical implication of this predilection for a circumferential growth pattern in left colon lesions is the higher incidence of obstruction in patients with distal large bowel cancer.

5.3.2 Microscopic Pathology

Adenocarcinoma originating from the epithelium of the colorectal mucosa remains the most common histology encountered. The WHO classification enlists a number of histologic variants such as mucinous, signet ring cell, medullary, micropapillary, serrated, cribriform comedo-type, adenosquamous, spindle cell, and undifferentiated. Neuroendocrine histology, lymphomas, and mesenchymal tumors are also observed, though rarely.

Invasion of the muscularis mucosae is the defining feature of invasive colorectal cancer. Although invasion through the lamina propria (basement membrane) is considered as invasive cancer at other gastrointestinal sites, in the colon and rectum, truly intramucosal lesions i.e. without breach of the muscularis mucosa (which may be involved) are considered as Tis, as the propensity for metastasis is negligible.

The degree of differentiation of conventional colorectal adenocarcinoma is defined by the degree of gland formation. Tumors with>95% gland formation are termed well differentiated, 50–95% gland formation is termed moderately differentiated, and < 50% gland forming tumors are mostly solid and are considered poorly differentiated carcinomas. Moderately differentiated adenocarcinoma is the most common histology encountered in clinical practice. Tumor grade is generally considered a stage-independent prognostic variable with high-grade tumors associated with poor survival.

Immunohistochemical markers most commonly utilized to define colorectal adenocarcinomas include cytokeratin (CK) 20, CK7, and CDX2 with positivity for CK20 and negativity for CK7 being the most prevalent immunophenotype [51] However, patterns contrary to the above are also seen. CDX2 is a marker for enteric differentiation and is positive in >90% of colorectal adenocarcinomas but lacks colorectal specificity [52].

5.4 Staging

The TNM staging system has been universally accepted as the standard staging system for colorectal cancer. Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 268–269, Chapter no.20: Colon and Rectum cancer. Definition of TNM and AJCC prognostic stage groups can be accessed at https://emedicine.medscape.com/article/2006674-overview [53]. Older systems of staging e.g. Dukes, Astler-Coller, etc. are now only of historic importance. Carcinomas that arise in the colon are spread by direct invasion of the layers of the colonic wall i.e., mucosa, submucosa, muscularis propria, subserosa, and serosa. This information is employed in assigning the T stage. The N and M staging denotes the invasion of lymphatics and blood vessels ultimately resulting in metastases at regional nodes (N) and at sites distant from the primary tumor (M). The number of metastatic sites involved is an important prognostic factor for colorectal cancer. Carcinomas may also grow in the subserosal tissue as discrete nodules of cells termed tumor deposits. The eighth edition of the AJCC cancer staging manual has made the following changes from the previous versions:

- M1c—Lists peritoneal carcinomatosis as a poor prognostic factor (Level 1 evidence).
- Clarification of the definition of tumor deposits (Level II evidence).
- Lymphovascular invasion—Reintroduced the L and V elements to better identify lymphatic (L) and vessel (V) invasion.
- Clarified the importance of MSI as a prognostic and predictive factor.
- Identified KRAS, NRAS, and BRAF mutations as critical prognostic factors which are also predictive.

5.5 Referrals Including Genetic Counseling

Hereditary colorectal cancer occurs due to pathogenic germ line mutations (i.e., mutations in the germ cells (sperm/ovum) and are therefore present in every cell of the body, as against sporadic mutations which are present only in the tumor cells) which are transmitted through generations with varying degrees of penetrance. Lynch syndrome and FAP are the two most common causes of hereditary colorectal cancer. Index cases with these genetic disorders often present with colorectal cancer as the first manifestation of the syndrome. It is important to identify and accurately classify these patients as hereditary colorectal cancer vis-à-vis sporadic disease. Once the ‘syndromic’ presentation of colorectal cancer has been confirmed through the recommended algorithm of genetic testing, the rest of the family members at risk can then be evaluated for the presence of the causative gene mutation and counseled regarding the associated colorectal cancer risk. There exist well-defined screening and treatment guidelines for hereditary colorectal cancer [54] as the incidence of cancer in these families could be as high as 60–100% depending on the syndrome involved.

5.6 Lynch Syndrome

Lynch syndrome is responsible for 3% of colorectal cancer cases worldwide and occurs due to a germ line mutation in at least one of the DNA mismatch repair genes (MLH1, MSH2, MSH6, PMS2). Lynch and colleagues estimated a three-fold risk of colorectal cancer compared to the general population, in families with a first-degree relative having this condition [55].

The DNA mismatch repair system is a cellular mechanism designed to repair short segment and single base pair mismatches. The system has two counterparts, one to detect areas of base mismatch and the second to repair them. The protein products of the MMR genes do not work in isolation but dimerize in their active form and work in pairs. A deficiency of a single protein, due to a mutation in the associated gene, would render the entire system nonfunctional. The phenotypic manifestation of a defective DNA mismatch repair system is the presence of unstable microsatellites. Microsatellites are long segments of DNA comprising multiple repeats of a particular sequence of base pairs. In the presence of a defective MMR system, the lengths of these microsatellites become unequal. This is termed microsatellite instability. When inaccurate DNA replication occurs due to ineffective mismatch repair affects the genes involved in one or more cellular growth controlling pathways, it results in uncontrolled cell growth i.e. cancer.

Observed by Warthin more than a century ago, Lynch and colleagues defined two clinical variants of this syndrome [56]:

- Lynch syndrome I or HNPCC (hereditary nonpolyposis colonic cancer).
- Lynch syndrome II or HSSCC (hereditary site-specific non-polyposis colonic cancer).

Features common to both variants include an autosomal dominance pattern, multiple primary colonic tumors, early age at onset, and predominance for the proximal large bowel. Lynch syndrome II is characterized by adenocarcinomas at extracolonic sites as well, particularly the endometrium and the ovary [57]. Other extracolonic sites involved in Lynch syndrome include the pancreas, stomach, hepatobiliary system, brain (Turcot syndrome), upper urothelium, and skin i.e. sebaceous adenomas (Muir-Torre syndrome).

5.6.1 Amsterdam II Criteria

These are a set of clinical criteria to detect possible families affected with HNPCC and were formulated in 1991 [58]. They include:

- At least three relatives who have a biopsy confirmed, HNPCC-associated cancer (colorectal, endometrial, ureter, renal pelvis, small bowel).
- At least two generations are affected.
- One is the first-degree relative of the other two.
- At least one relative was diagnosed at ≤50 years of age.
- Familial adenomatous polyposis has been excluded.

The criteria have been modified to include the following:

- Two cases of colorectal cancer when families are small (one younger than 55 yrs. old).
- Two cases of colorectal cancer and one of endometrial cancer or other early-onset cancer.

5.6.2 Bethesda Guidelines

Formulated during the National Cancer Institute workshop on HNPCC in 1997 and revised in 2004, the Bethesda guidelines seek to address the underestimation of the true incidence of HNPCC by the Amsterdam criteria. They also assist in selecting patients to be analyzed for Microsatellite instability (MSI). MSI testing is recommended in individuals who meet any of the following criteria:

- Colorectal cancer is diagnosed at ≤50 years of age.
- Two HNPCC-related cancers (synchronous or metachronous).
- Colorectal cancer with MSI-H histology at ≤60 years of age.
- A first-degree relative who has HNPCC-related cancer, one of the cancers diagnosed at ≤50 years of age.
- Colorectal cancer in two or more first- or second-degree relatives with HNPCC-related tumors [59].

5.6.3 Familial Adenomatous Polyposis (FAP)

Mapped to the *APC* gene on chromosome 5q21, this hereditary polyposis syndrome is transmitted in an autosomal dominant fashion. Even though Virchow reported a 15-yr old boy with multiple colonic polyps as early as 1863, the demonstration of the *APC* gene as the responsible mutation was established only in 1986, by Lemuel Herrera. This gene has near 100% penetrance. The median age at presentation with colorectal polyps is 29 yrs. and the average age of presentation of FAP-related colorectal cancer is 39 yrs.

Characteristic features include multiple colonic polyps, gastric, duodenal a periampullary polyps with occasional extraintestinal manifestations like osteomas, brain tumors, desmoids, congenital hypertrophic retinal pigment epithelium (CHRPE) and epidermoid cysts. The presence of more than 100 adenomatous polyps in the large bowel is nearly diagnostic of FAP. Patients with multiple colonic polyps but less than 100 may have an attenuated form of the syndrome. Attenuated FAP should be suspected in a patient with a cumulative history of >10 to 20 colorectal adenomatous polyps. Gastric polyps are mostly fundic gland hyperplasia rather than adenomatous polyps and therefore have limited malignant potential. Duodenal polyps on the other hand are adenomatous and hence premalignant and confer an increased risk of periampullary carcinoma. Eponymous syndromes related to FAP are *Gardnersyndrome* (colonic polyps, epidermal inclusion cysts, and osteomas) and*Turcotsyndrome* (brain tumors like cerebellar medulloblastomas and glioblastomas).

5.6.4 Genetic Testing and Counseling

The possibility of hereditary colorectal cancer, i.e., FAP (including attenuated FAP and FAP variants) and Lynch syndrome should be suspected based on the criteria detailed above. Such individuals should then be evaluated in a dedicated genetic clinic. Detection of a pathogenic germ line mutation establishes a diagnosis of hereditary colorectal cancer and family members can then be offered genetic testing to determine whether they have inherited the same pathogenic mutation. Carriers of pathogenic mutations will benefit from increased surveillance while family members who have not inherited the mutant gene qualify as average-risk individuals and can undergo routine screening.

Failure to detect a pathogenic mutation is less helpful, as undefined, inheritable genetic processes may still be present. The *APC* gene mutation may not be identified in up to 20% of patients with a well-documented clinically evident FAP syndrome and a negative gene test result may occur in nearly 50% of families with a suspicion of Lynch syndrome. Although intensive surveillance is still recommended for such families it may however be stopped earlier if no manifestation of the disease presents itself.

6 Principles of Management

Radical surgical resection forms the mainstay in the treatment of colon cancer and is more often than not the first treatment modality to be offered. Even in the setting of locally advanced disease, surgery is recommended as the first treatment modality if an R0 resection can be achieved. This is in contrast to rectal cancer, where neoadjuvant therapy for locally advanced disease plays a vital role in reducing local recurrence. There is a dearth of evidence for neoadjuvant therapy in locally advanced colon cancer. As additional evidence from ongoing trails becomes available, the role of neoadjuvant chemotherapy in colon cancer will be further elucidated in the near future.

Probably, the most significant paradigm shift in the last decade has been the adoption of treatment with curative intent, in a select group of patients with metastatic colorectal cancer. Effective multidisciplinary treatment has offered survival rates of 45–50% in this select patient group [60–62].

The following section will present a detailed account of the role of surgery, chemotherapy, and radiation in the multidisciplinary management of colon cancer.

7 Surgical Management

7.1 Endoscopic Resection

The classical adenoma-carcinoma sequence as postulated by Vogelstein [33] states that colorectal cancer arises from adenomatous polyps which acquire sequential genetic mutations that ultimately result in the malignant phenotype, occurring over a time period of 8–10 years. This fact provides a window where in timely endoscopic resection of adenomatous polyps can preclude their malignant transformation.

Endoscopic management of colorectal polyps is achieved by two basic techniques viz. endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD). EMR is applicable for polypoid lesions and involves the injection of saline into the submucosa, creating a cushion between the mucosa and the muscularis. The elevated polyp is then resected with an electrocautery snare. The absence of a 'lift' sign on submucosal injection indicates submucosal infiltration, often precluding an endoscopic approach. ESD on the other hand utilises specialized endoscopic knives to create a mucosal incision followed by subsequent dissection in the submucosal space. This technique enables larger and more sessile lesions to be resected en-bloc. According to a recent meta-analysis, a 96.3% cure rate with endoscopic polypectomy can be achieved for polyps >2 cm, with a 1.5% perforation rate and only 8% of patients proceeding to subsequent surgery [63].

Infiltration of the muscularis mucosa into the submucosa as seen on histopathological examination of endoscopically resected polyps is required to establish a diagnosis of invasive adenocarcinoma. Purely intramucosal lesions do not show lymphatic spread and are not considered invasive. Invasive adenocarcinoma in a pedunculated polyp, resected endoscopically en-bloc with a negative margin, grade 1/2 on histology and no evidence of angiolymphatic invasion does not need any further management. These patients can be kept under surveillance. However, there is no consensus on what constitutes a negative margin on endoscopically resected polyps; 1 mm, 2 mm, or absence of malignant cells at the cauterized edge are all accepted definitions. We consider ≥1 mm a negative margin and are comfortable keeping these patients under surveillance. Should there be any one adverse factor (viz. positive margin, Grade3/4 or angiolymphatic invasion), or a piece-meal resection precluding accurate evaluation of margin status, a subsequent radical colectomy should be considered, weighing the risks and benefits of radical surgery.

Endoscopically resected sessile polyps show a higher propensity for adverse outcomes in terms of local recurrence, metastatic disease, and mortality [64–66]. However, with advanced ESD techniques, sessile polyps resected en-bloc, with negative margins and no adverse factors can be effectively managed endoscopically [67, 68]. When treating early colon cancer, another important issue to consider is the extent of submucosal infiltration. Although all submucosal infiltration is classified as T1 disease [53], the incidence of lymph node metastasis exponentially increases with the depth of submucosal involvement. Lesions involving the Upper third of the submucosa (SM1) have a 1–3% risk of lymph node metastasis. This increases to 8–10% if the middle third is involved (SM2) and may go up to 23–30% if the entire submucosa is infiltrated (SM3) [69, 70]. Therefore, endoscopic resection is only considered adequate for SM1 lesions and for that matter, an R0 endoscopic resection, even with advanced ESD is only likely in these lesions with superficial submucosal infiltration especially if they are sessile. A recent systematic review showed a very low incidence of SM1 lesions in ESD resected specimens and a still lower rate(6%) of curative resections calling for caution in the use of this technique in colorectal cancer [71].

7.2 Radical Colectomy

A radical colectomy is not a mere resection-anastomosis of the colon. Strict adherence to the basic oncological principles of an en-masse resection of the tumor along with its draining lymph nodes is mandatory to perform a radical colon resection. As the draining lymph nodes follow the vascular supply of the colon, a knowledge of the colonic blood supply is essential to be able to dissect and ligate these vessels at their origin, ensuring a radical lymphadenectomy.

The abdominal colon is supplied by the ileo-colic, right colic, middle colic, left colic and sigmoid vessels Fig. 1 The location of the primary tumor determines which vascular pedicles need to be divided which in turn defines the surgical templates for radical colonic resection (Table 2). It is also important to note what is considered regional lymph nodes for tumors at different locations in the large bowel, which can be accessed at https://training.seer.cancer.gov/colorectal/anatomy/lymph-nodes.html [53].

A standard right hemicolectomy is oncologically adequate for tumors in the caecum and ascending colon. However, if the lesion reaches the hepatic flexure the middle colic pedicle needs to be ligated at its origin, to perform an extended right hemicolectomy. Mid- transverse colon lesions can be oncologically resected with a transverse colectomy taking the middle colic vascular pedicle,

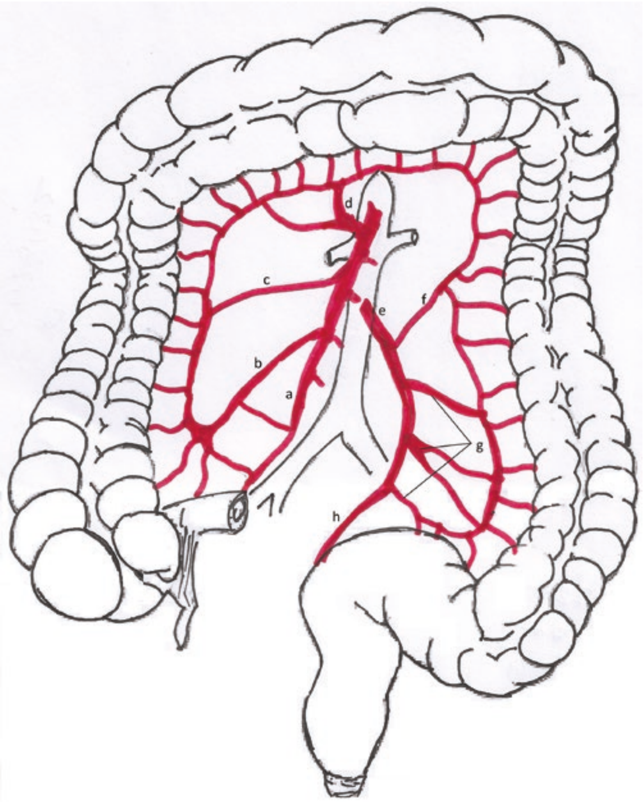

Fig. 1 Vascular anatomy of the colon

Table 2 Radical colectomy: surgical templates

Location of Primary Tumour	Vascular pedicles are to be divided	Colon resection type
Caecum and ascending colon	Ileocolic, right colic, right branch of the middle colic	Right hemicolectomy
Hepatic flexure	Ileocolic, right colic, middle colic at its origin	Right extended hemicolectomy
Transverse colon	Middle colic	Transverse colectomy
Descending colon	Left colic, left branch of the middle colic	Left hemicolectomy
Sigmoid colon	Sigmoid vessels	Sigmoid colectomy
Rectosigmoid	Sigmoid vessels, inferior mesenteric artery	Anterior resection

however, it is often technically challenging to mobilize and anastomose the hepatic and splenic flexures following resection of the transverse colon. Additionally, the colonic blood supply via the marginal artery is most tenacious at the flexures leading to a high risk of vascular compromise at the anastomosis following a transverse colectomy. Therefore, though it is oncologically adequate, a transverse colectomy is rarely performed. A right extended hemicolectomy is our preferred choice for transverse colon lesions.

Tumors between the distal transverse and proximal descending colon deserve special attention. Involvement of the distal transverse colon and/or splenic flexure theoretically necessitates resection of the main middle colic pedicle in order to remove all regional nodes. This results in a very short stump of transverse colon making the subsequent colocolic anastomosis technically difficult. An extended right hemicolectomy with ileo-descending anastomosis is oncologically adequate, and technically easier, but comes with the price of resection of additional large bowel and the ileocaecal valve with its resultant functional consequences. There is very little literature to guide the choice of procedure for tumors at this location. In a recent retrospective review from the UK, both an extended right hemicolectomy (ileocolic, right colic, middle colic and ascending branch of the left colic vessels) and left hemicolectomy (left colic and left branch of the middle colic vessels) were shown to have equivalent outcomes in terms of perioperative morbidity and overall survival, making either procedure a suitable choice for tumours at this location [72]. This was further confirmed in a systematic review and metaanalysis [73].However, in the setting of obstructing tumours at and around the splenic flexure with doubtful caecal viability, a right extended hemicolectomy would be the procedure of choice.

The inferior mesenteric nodes are considered regional nodes for tumours in the left colon (descending, sigmoid, rectosigmoid). We perform a nodal dissection right till the root of the inferior mesenteric artery (IMA) for all left colon lesions irrespective of what vascular pedicles are eventually ligated. A sigmoid colectomy, ligating the sigmoid vessels while preserving the left colic and superior rectal pedicle is oncologically adequate for lesions entirely within the sigmoid colon. While this is feasible for lesions at the apex of the sigmoid loop, we prefer to include the left colic for sigmoid tumors at or near the descending-sigmoid junction and the superior rectal artery (i.e. anterior resection) for lesions towards the rectosigmoid.

7.3 Complete Mesocolic Excision (CME)

When one considers the patterns of failure following radical colon and rectal resection it becomes evident that while both have a nearly equal propensity for liver metastasis (colon 69.6%, rectum 67.4%), Colon cancer is more likely to fail in the abdomen while rectal cancer is associated with higher incidences of lung and brain metastasis [74]. While this is largely due to the fact the colon is an entirely abdominal organ, it cannot be denied that radical resections for colon cancer have been less standardized as compared to total mesorectal excision (TME) for rectal cancer. Preservation of the mesorectal envelop is the hallmark of a complete TME, which has been shown to drastically reduce local recurrence rates [75].

Hohengerber et al. introduced a similar concept (CME) to standardize colon resection within an intact mesocolic envelop [76]. Essentially this technique has three components, namely dissection in the embryological plane to maintain an intact mesocolic envelop (Fig. 2), a central vascular tie removing all draining lymph nodes at the root of vascular pedicles(Fig. 3), and resection of a sufficient length of the adjacent large bowel (10 cm on each side) to remove all pericolic nodes.

The incidence of metastasis to lymph nodes at the root (i.e., N3 nodes as classified by the Japanese Society for Cancer of the Colon and Rectum) varies from 7–36% depending on the location of the primary tumor [77, 78]. Moreover, removal of these N3 nodes could lead to a stage migration (from Stage II to Stage III) of 4.5% with a rate of skip metastasis (i.e. involvement of more proximal lymph node stations without involvement of distal stations) of nearly 20% [79]. In view of these facts, it is logical to hypothesize that a more radical lymphadenectomy at the origin of colonic vascular pedicles would result in lower local recurrence and possibly improve survival outcomes.

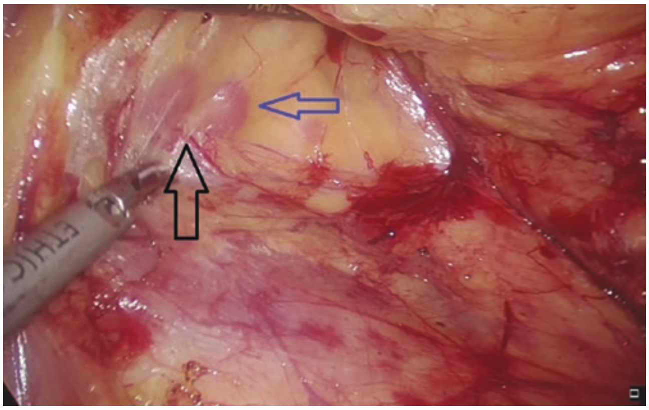

Fig. 2 Mesocolic plane in right colon CME (blue arrow—pericolic nodes; black arrow—the mesocolic plane of dissection)

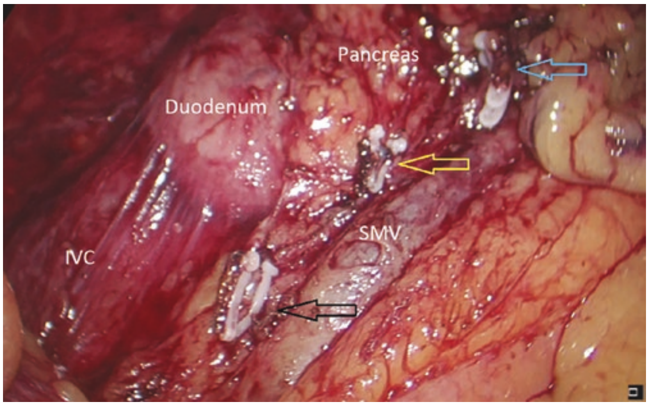

Fig. 3 Right colon bed after CME (blue arrow—middle colic pedicle; yellow arrow—right colic pedicle; black arrow—ileocolic pedicle)

There have been three systematic reviews in the last 3 years evaluating the role of CME in surgery for colon cancer [80–82]. All three reviews support a superior pathological specimen after CME as compared to conventional colectomy in terms of a longer length of resected bowel, completeness of mesocolic excision, length of the vascular pedicle, and a greater lymph node harvest. However, there is some evidence to suggest that this more radical approach could be associated with a higher incidence of injury to other organs (superior mesenteric vein, spleen, colon) [83], as well as greater intraoperative blood loss and more post-operative complications, though not translating to increased post-operative mortality [82]. Improvements in survival (disease-free survival and overall survival) and local recurrence with CME, though not uniformly reported in all series have been corroborated in a large number of reports, especially for Stage III disease [82, 84–87].

The technique also lends itself to the laparoscopic approach. A recent metaanalysis comparing laparoscopic and open complete mesocolic excision for colon cancer confirmed the equivalence of laparoscopy in terms of quality of the resected specimen, lymph node retrieval, and length of the vascular pedicle. The laparoscopic group also showed a lower rate of blood transfusions, a faster return of gastrointestinal function, fewer post-operative complications, and a better 3-year overall and disease-free survival [88]. The greater length of bowel resected and the extensive lymphadenectomy at the root of the vascular pedicles, as they take off the superior mesenteric artery and vein (with possible damage to the nerve plexus) could theoretically lead to long-term bowel dysfunction and suboptimal quality of life. However, in a population-based questionnaire study, there was no difference in the long-term bowel function and quality of life between patients undergoing CME or conventional resection for right colon cancer [89]. At the Tata Memorial Centre, we have adopted complete mesocolic excision as a standard of care for all elective radical colectomies.

7.4 The Extent of Colectomy in the Setting of Familial Colorectal Cancer

The two most common familial colorectal cancer syndromes are Familial Adenomatous Polyposis and Lynch syndrome. The surgical management of colon cancer in the setting of these syndromes differs from non-familial colon cancer in the extent of colectomy that is recommended.

For patients with colon cancer with FAP, i.e.,>100 polyps in the colon and rectum, surgical options include a total proctocolectomy (TPC) + Ileal pouch-anal anastomosis (IPAA)/ permanent ileostomy or subtotal colectomy + ileo-rectal anastomosis (IRA). In the presence of extensive colonic polyposis (i.e. >1000 polyps) TPC is recommended. However, if polyposis is not so extensive and there is evidence of rectal sparing i.e. <10 rectal adenomas all of which are amenable to endoscopic resection, a subtotal colectomy + IRA can be performed. If patients are at risk for desmoid tumor formation, TPC + IPAA is the recommended procedure as subsequent desmoid formation in the small bowel mesentery will preclude future IPAA.

Patients with colon cancer and attenuated FAP or suspected attenuated FAP i.e. >10 but <100 polyps, pose a different problem and every case needs to be managed on an individual basis. Adenomatous polyps, especially high-risk adenomas (i.e., tubular adenomas ≥10 mm, adenoma with villous histology or high-grade dysplasia) need to be resected completely. If the template of colon resection for the primary colonic tumor encompasses the polyps, these will be resected with the standard recommended colectomy as per the tumor location. If there are polyps outside the template of colonic resection they need to be removed endoscopically preferably prior to colonic resection. High-risk adenomas, not amenable to endoscopic resection may be addressed surgically at the same sitting either by extending the segment of colon resected or by full-thickness excision/segmental colectomy depending on the size and location of the polyps with respect to the primary tumor.

Patients with colon cancer with proven Lynch syndrome (documented germ line mutations in one of the DNA mismatch repair genes) or Hereditary Nonpolyposis Colorectal Cancer (HNPCC, i.e., patients or families who fulfill Amsterdam criteria for Lynch syndrome) should be offered total abdominal colectomy + IRA, irrespective of the site of colon primary [90]. As the risk of endometrial and ovarian cancer is high in women with Lynch syndrome, prophylactic hysterectomy with bilateral salpingo-oophorectomy should be offered or should at least feature in the preoperative counseling of risk vs., benefit in this group of patients.

7.5 Minimally Invasive Surgery for Colon Cancer

Minimal-invasive surgery in colorectal cancer has been in vogue since 1990 [91]. The patient benefits in terms of decreased hospital stay, decreased postoperative pain and faster recovery of bowel function are now evident. The oncological safety of laparoscopy for colon cancer, though initially a matter of concern, has now been confirmed by a number of well-conducted randomized trials. So far, there have been three main trials that have addressed the issue of laparoscopy in colon cancer namely, the COST trial [91] the COLOR trial [92], and the MRC-CLASICC trial [93].

The COST (Clinical Outcomes of Surgical Therapy Study Group) trial was a randomized, non-inferiority trial conducted over 48 institutions in North America with 872 patients [91]. The primary end point was time to tumor recurrence with overall survival (OS) and disease-free survival (DFS) as secondary end points. At the end of 3 years, the recurrence rates (RR) and OS were found to be similar—16% and 86% in the laparoscopy arm vs. 18% and 85% in the open arm respectively. There was also no difference in the time to recurrence. The recurrence rates in surgical wounds were found to be less than 1% in both the groups, laying to rest the issue of port site metastasis which was a concern at that time. The patients in the laparoscopy arm did see benefits in terms of decreased hospital stay and decreased use of parenteral (narcotics) and oral analgesics. The equivalence of laparoscopy in terms of long-term outcomes was confirmed at 5 years, with no significant difference in the DFS, OS, and RR between both the groups, finally concluding that laparoscopic colectomy for curable colon cancer is not inferior to open surgery [94].

The COLOR (COlon carcinoma Laparoscopic or Open Resection) trial was a European, multicenter, randomized, non-inferiority trial [92] conducted over 29 centers with 1076 patients. The primary end point was DFS at 3 years and the secondary end points were OS, post-operative morbidity, local recurrence (LR) at port sites, and blood loss during surgery. The pre-specified non-inferiority boundary was kept at 7% difference. They found that the 3-year DFS was 74.2% in the laparoscopy group and 76.2% in the open group and the difference in DFS was 2.0% (95% CI 3.2–7.2), the upper limit of the 95% CI for the difference just exceeding the predetermined non-inferiority boundary of 7%. However, the authors stated that as the difference in DFS between the groups was small and an as-treated analysis did not show a significant difference in DFS. the implementation of laparoscopic surgery into daily practice was justified. Additionally, the 3-year OS was also not significantly different between the groups—81.8% (lap) vs. 84.2% (open) [95]. A 10-year unplanned follow-up study with only 256 Dutch patients was reported in 2017 which concluded that laparoscopic surgery for non-metastatic colon cancer is associated with similar rates of DFS, OS, and recurrences as open surgery at 10-year long-term follow-up [96].

The third important trial was the MRC-CLASICC trial (Medical Research Council trial of Conventional versus Laparoscopic-Assisted Surgery in Colorectal Cancer) [93] conducted in the UK over 27 centers with 794 patients for both colon and rectal cancers. The primary short-term endpoints were mainly circumferential radial margin (CRM) positivity, longitudinal margin positivity, and in-hospital mortality rates. The secondary short-term endpoints were complication rates, quality of life (QOL), and intra-op transfusion requirements. The primary long-term end points were 3-year OS, 3-year DFS, and 3-year local recurrence rates. There was no difference in the in-hospital mortality rates overall and the rates of positive resection margins were also similar. The CRM rate for colon cancer was 5% vs. 7% (open vs. lap) which was not significant. Complication rates or transfusion requirements also did not differ between the groups. On 3 years [97], 5 years [98], and 10 years [99] follow-up, there was no difference in OS, DFS, and recurrence rates between both the groups. At the 10-year follow-up, intra operative conversions were associated with worse OS and DFS, and right colonic cancers showed an increased propensity for local recurrence vis-a-vis left colonic lesions (14.7 vs. 5.2% ($P = 0.019$) [99].

With all three trials reporting similar short- and long-term outcomes, laparoscopy for colon cancer can be considered equivalent to open surgery at centers that demonstrate the required expertise.

7.6 Management of the Obstructed Colon Primary

About 15–40% of patients with colon cancer present as a surgical emergency with perforation or obstruction. Left-sided colonic lesions are more prone to cause obstruction vis-a-vis right colon lesions due to the smaller luminal diameter of the left colon and the more solid consistency of the stool at this portion of the bowel. Rarely, a right colon lesion can also lead to obstruction especially if it is in close proximity to the ileocaecal valve. Obstructing right colon lesions can usually be managed with a radical right colon resection and primary anastomosis in the majority of cases.

The management of an obstructing left colon primary poses a unique challenge as both the emergent nature of the surgical obstruction and the management of the malignancy need to be addressed. Additionally, there is rarely time to subject these patients to a complete staging protocol. Every patient with an obstructing colon primary is unique, with varying degrees and durations of obstruction, differing hemodynamic responses, varied co-morbid illnesses, and different levels of surgical fitness. Therefore, a uniform algorithm cannot be recommended for all such patients, rather, there exist a number of surgical options as discussed below, that can be considered in the management of these patients.

7.6.1 Diversion Colostomy

A diversion colostomy is aimed only at tiding over the surgical obstruction and is associated with the least surgical stress among all available surgical options. Although this may be the best option in the elderly, frail, malnourished, or hemodynamically unstable patient, for the large majority, resection of the primary obstructing lesion can be achieved without an increase in morbidity or mortality [100]. Care must be taken to confirm the viability of the large bowel on the exploration of every patent with an obstructing colon primary. A closed-loop obstruction (due to a competent ileocaecal valve) of substantial duration with colonic dilatation near 10 cm may lead to colonic wall ischemia and impending perforations. Colonic resection remains the only viable surgical option in the presence of non-viable bowel.

7.6.2 Hartmann's Procedure

A Hartmann procedure achieves a radical resection of the colonic primary at the same time avoiding the risk of an anastomotic leak. This approach is preferred whenever there exists a high possibility of an anastomotic leak, long-standing obstruction with an oedematous bowel wall precluding a primary anastomosis, an unfit or malnourished patient, or in the presence of hemodynamic instability.

A Hartmann procedure requires a second operation to re-establish intestinal continuity. These patients may face stoma complications like prolapse and stenosis and nearly one-third of patients with Hartmann's procedure may never have their stoma reversed [101]. Hartmann reversal is a technically demanding procedure, especially in cases of a short residual rectal stump, and is associated with leak rates of nearly 16% [102]. It is for these reasons that primary anastomosis is preferred whenever feasible.

7.6.3 Primary Resection and Anastomosis

In uncomplicated left-sided malignant bowel obstruction, a primary resection and anastomosis have been shown to be safe and feasible and are the preferred surgical approaches [103]. However, it is universally accepted that some form of colonic decompression, either manual decompression or on-table colonic lavage is mandatory prior to a colo-colic anastomosis in a one-stage procedure for obstructed left colon cancers [104]. Both manual decompression and on-table colonic lavage are equally effective in achieving colonic decompression in this setting [105–107]. A third option is to perform a subtotal colectomy with a ileo-colic anastomosis. This would effectively remove the obstructed and fecal-loaded colon and achieve as it were a "surgical decompression." Although one randomized trial [108] showed no difference in morbidity and mortality between on-table colonic lavage and subtotal colectomy, subtotal colectomy was associated with a greater number of bowel motions post-operatively. We prefer on-table colonic lavage or manual decompression with primary anastomosis for uncomplicated malignant left colon obstruction and reserve subtotal colectomy in situations of questionable viability of the proximal large bowel, synchronous lesions, and in the setting of known hereditary cancer syndromes.

7.6.4 Endoscopic Colonic Stenting

Deployment of self-expanding metallic stents across the obstructing colonic lesion serves as an effective way to tide over the surgical emergency, appropriately stage the disease, and offer the patient a one-stage definitive surgical resection in the majority of cases. Although this technique does require expertise, 85% of patients can be successfully decompressed using endoscopic stents as a bridge to surgery and 95% of these patients will have a one-sage colon resection in the following 9–10 days [109]. The use of endoscopic stents as a bridge to surgery is associated with lower post-op complications, a lower stoma rate, and a lower incidence of surgical site infection [110]. Additionally, a subsequent laparoscopic colon resection is also feasible [111].

7.6.5 Multivisceral Resection for Colon Cancer

Nearly 10% of patients with colon cancer will present with locally advanced disease invading adjacent organs [112]. More often than not this will be appreciated intraoperatively as adherence to adjacent organs. A contemporary series of multi-visceral resections for colon cancer reported a 63.6% incidence of actual tumor involvement on final histopathology [113]. Given the high percentage of pathological T4b on final histopathology, and the inferior outcomes associated with the dissection of such adhesions [114, 115], as a surgical principle, it is prudent not to disengage such tumor adherence but rather consider a multi-visceral resection where ever feasible.

For locally advanced primary colon cancer, the most common organs to be involved are the abdominal wall and small bowel [114, 116, 117] which can be resected without additional morbidity. However, the sigmoid colon, duodenum, pancreas, spleen, stomach, and bladder can all be involved depending on the location of the primary tumor. The feasibility of a multi-visceral resection has been shown in a number of reports [113, 116–119]. However, these are complex procedures associated with higher morbidity rates of nearly 25% to 49% and a post-operative mortality of nearly 7% [116, 118, 120]. A careful evaluation of the risks and benefits on a case-to-case basis is warranted when considering such an approach. Although associated with higher morbidity, if an Ro resection can be accomplished, 5-year survival rates of 80–86% [113, 116] can be achieved. When compared with a standard colectomy stage for stage, similar 5-year survival rates are observed [114, 118, 121].

Perhaps the most challenging of all multi-visceral resections for locally advanced colon cancer is an en-bloc pancreaticoduodenectomy for right colon lesions infiltrating the duodenum or pancreatic head. In many instances, the lateral wall of the duodenum may be resected en-masse with the primary at the point of infiltration, achieving an R0 resection and at the same time avoiding the morbidity of an en-bloc pancreaticoduodenectomy. Duodenal closure may be achieved either primarily or with the help of a roux-en-y jejunal loop, depending on the magnitude of the duodenal defect. Although there is a report that suggests that such lesser resections could be associated with an inferior outcome viv-s-vis a formal pancreaticoduodenectomy [122], data on this rare clinical situation is sparse and a multidisciplinary decision needs to be made on a case-to-case basis. However, though associated with more morbidity, an en-block pancreaticoduodenectomy is not associated with increased postoperative mortality and perhaps offers the best outcomes at centers with the required expertise [122–124].

7.6.6 Surgical Management of Metastatic Colon Cancer

Nearly 50% of patients with colorectal cancer will develop metastatic disease at some point during their lifetime. Metastatic disease at initial presentation may occur in 20% of patients. These patients have a worse prognosis as compared to patients with a metachronous presentation [125]. Modern polyagent chemotherapy alone can offer a median survival of 30 months [126]. This may be further enhanced with the addition of targeted agents. Surgical resection of metastatic disease offers a survival advantage in a select group of patients. As there are numerous treatment options available and variations in the sequence in which they are administered, patients with metastatic disease are best evaluated in a multidisciplinary clinic. The liver (69.6%), lung (30,7%), and peritoneum (28.8%) are the three most common sites of metastasis in colon cancer [74]. A detailed description of the surgical management of metastatic disease at these three subsites is beyond the scope of this chapter, however, only the essential principles will be presented here.

Perhaps the first issue to be resolved in the evaluation of a patient with stage IV colon cancer is the determination of treatment intent, i.e., palliative or curative. Treatment with curative intent can be offered to patients in whom the primary along with all sites of metastatic disease are resectable or amenable to some modality of definitive local treatment. A metastatic disease that is evidently unresectable at the outset would, as a general rule, be treated with chemotherapy with palliative intent. There are a small group of patients who though unresectable at presentation, may become resectable after a good response to systemic chemotherapy. At the outset these, patients are best labeled “potentially resectable” and their final treatment intent is decided on the response to systemic chemotherapy.

The second issue to consider is whether the colon primary is symptomatic or not. Intraluminal bleeding (often requiring multiple blood transfusions) and luminal obstruction are the two most common presentations of a symptomatic primary. Bleeding and obstructing lesions can be effectively managed by resection. However, in the setting of unresectable metastatic disease or a bulky primary with frank T4b disease on radiological imaging, a proximal diversion stoma would be the more prudent option. Asymptomatic primaries in the setting of the unresectable metastatic disease usually do not require surgical intervention, as >90% of these tumors never become symptomatic during chemotherapy [127]. Resection of the primary may be considered if using bevacizumab due to the risk of tumor perforation [128, 129]. It cannot be overemphasized that the treatment plan has to be individualized for every patient with stage IV colon cancer and this is best done in a multidisciplinary clinic.

7.6.7 Surgical Options for Liver Metastases

Only about 10–30% of liver metastases are resectable at presentation [130, 131]. However, 70–80% of patients will show some clinical response to systemic chemotherapy [132]. Coupled with local ablative therapies, a small number of initially unresectable liver metastasis may ultimately be feasible for metastasectomy [133]. The 5-year survival with chemotherapy and liver resection is roughly 50% [134]. Unfortunately, nearly 80% of patients undergoing liver metastasectomy will have intrahepatic recurrence at some point [135].

Options for liver-directed therapy include surgical resection and local ablative therapy with radiofrequency or microwave ablation. Surgical resection is preferred over local ablative therapies as it is associated with better long-term outcomes. Radiofrequency/microwave ablation could be considered for lesions <3 cm especially in deep-seated, centrally located lesions, patients unfit for liver metastasectomy, in conjunction with hepatectomy in patients with bilobar disease, and in the setting of unresectable disease along with systemic chemotherapy.

Liver resection may be in the form of a major hepatectomy (four or more segments [136]), less than a major hepatectomy, or extended hepatic resection. The two main issues to be considered when planning a liver resection for colorectal liver metastasis are the need for a margin negative resection and the preservation of adequate liver volume and function. In a normal liver, at least 20% of the total liver volume is required in the liver remnant following resection. This is increased to at least 30% in the presence of chemotherapy-associated liver injury and 40% in the presence of hepatic fibrosis/cirrhosis. Care should be taken to ensure at least two contiguous liver segments with intact portal and arterial inflow, venous outflow, and biliary drainage. Liver metastasectomy is generally contraindicated in the presence of unresectable extrahepatic metastasis, significant portal lymphadenopathy, progressive disease if pre-operative chemotherapy is used, and in the patient unfit for major surgery.

Liver lesions <2 cm may not be visible on imaging or intraoperative ultrasound in 10–38% of cases [137]. However, these are rarely complete responses and residual viable malignant cells can be demonstrated in 80% of these 'vanishing' lesions [138]. One option is to coil localize these small liver lesions prior to the administration of chemotherapy. This is an outpatient procedure where a small metallic coil is introduced into or adjacent to the lesion usually under ultrasound guidance. This serves as a marker for future liver-directed therapy should the lesion disappear after chemotherapy.

Synchronous liver metastasis poses a unique problem with respect to the timing of liver metastasectomy with respect to the resection of the primary. There exist three options; the conventional approach (colon resection, followed by liver resection with or without chemotherapy in the interim); the synchronous resection (both colon and liver at the same sitting),and the liver first approach (liver resection followed by colectomy with or without chemotherapy in the interim). A synchronous approach when resection of up to three liver segments is involved is generally considered safe and feasible [139, 140]. However, a combination of a major hepatic lobectomy with complex colorectal resection may lead to increased morbidity [139, 141, 142]. The liver first approach is particularly suitable for a small primary with large volume but resectable liver disease. The main concern here is the fact that chemotherapy-associated liver injury after numerous cycles may preclude subsequent major liver resection. The liver-first approach has shown to be both safe and feasible and has been adopted at some centers as a standard of care [143–145]. A number of meta-analyses supported a synchronous approach for resection of colorectal liver metastasis [146] even in patients undergoing major hepatectomy with complex colorectal resection [147, 148]. However, it should be noted that this is data from high-volume centers where multidisciplinary teams are involved in the management of these patients. To summarize, wherever feasible a synchronous approach is preferred. If not feasible a staged approach with either colon or liver first is acceptable.

7.7 Surgical Options for Lung Metastases

Lung metastasis in colorectal cancer is rarely seen in isolation and usually present in conjunction with other metastatic sites [149]. Rectal cancer has a higher propensity for pulmonary metastasis as compared to a colon primary [74]. The 5-year survival rates after pulmonary metastasectomy range from 24–56% [150]. However, recurrences are common and can be as high as 80% at 2 years [151].

Pulmonary wedge resection with negative margins can be achieved in the majority of patients with very few requiring formal lobectomy to achieve negative margins. Local ablative techniques with radiofrequency and microwave ablation are also applicable in the lung in select cases and can be utilized if repeat metastasectomy is not feasible or if competing c0-mormid illnesses preclude surgical resection.

7.8 Surgical Options for Colorectal Peritoneal Metastasis

The incidence of peritoneal metastasis in colorectal cancer is about 8–20% [152]. Peritoneal metastasis has the worst prognosis among other metastatic sites with very few patients actually achieving long-term control [153]. In the past, peritoneal metastasis from colorectal cancer was treated with palliative intent. Today a subgroup of patients can be offered cytoreductive surgery (CRS) and heated intraperitoneal chemotherapy (HIPEC)with results that supersede those of systemic chemotherapy alone.

Cytoreductive surgery was popularised by Sugarbaker [154] and forms the mainstay in this treatment modality. Essentially this technique involves a detailed exploration of the entire peritoneal cavity to accurately establish the volume of peritoneal disease which is objectively scored with the Peritoneal Carcinomatosis Index (PCI) (Fig. 4) [155]. An attempt is then made to resect all macroscopic peritoneal disease which may involve stripping of all visceral peritoneum and multiple organ resections as per a defined procedure [156]. The residual disease and the end of this part of the procedure are scored on a completeness of cytoreduction score (CC Score, Table 3) [155, 157]. The best results are seen if CC-o or CC-1 can be achieved. A cut-off of 2.5 mm as the maximum residual tumor size after CRS has probably been determined by the maximum depth of drug penetration during HIPEC [158]. There is no consensus on the drug, dose, temperature, or contact time for HIPEC with each center adopting its own protocol. Oxaliplatin, carboplatin, doxorubicin, and irinotecan, using a perfusate volume of 2–5 L, at a temperature of 40–43 degrees centigrade for a contact time of 30–120 min have been used. Following HIPEC the residual solution is evacuated, the peritoneal cavity irrigated and the abdomen closed to complete the procedure.

Patient selection both from a disease volume standpoint, i.e., PCI and with respect to surgical fitness are essential for a favorable outcome and these cases are best discussed in a multidisciplinary clinic. A PCI >15–17 is generally a contraindication for CRS + HIPEC as these patients are associated with the worst prognosis. A consensus statement [159] from leading centers in CRS + HIPEC stated 8 factors that increased the probability of achieving complete cytoreduction viz. ECOG status ≤2, no evidence of extra-abdominal metastasis, up to 3 small, resectable, liver metastasis, no evidence of biliary obstruction, no evidence of ureteral

obstruction, no evidence of intestinal obstruction at >1 site, limited small bowel involvement and small volume disease in the gastrohepatic ligament.

The only randomized controlled trial reported to date is by Verwaal et al. [160]. In this study 105 patients were randomized into 2 arms—Systemic chemotherapy (5FU + Leucovorin)with or without palliative surgery or the experimental arm of CRS + HIPEC followed by the same systemic chemotherapy. The primary endpoint was survival. At a median follow-up of 21.6 months, the median survival was 12.6 months in the standard arm and 22.3 months in the experimental arm ($p = 0.32$). CRS + HIPEC was associated with a treatment-related mortality of 8%. Intestinal leakage and fistula were the main morbidity. The best results were seen in patients with involvement of up to 5 regions of the abdomen and in patients in whom all macroscopic diseases could be surgically excised. The group published their results after an 8-year follow-up [161] which showed that there were 4 patients still alive in the standard arm (2 with and 2 without disease), and 5 patients alive in the HIPEC arm (2 with and 3 without disease). However, the median progression-free survival was 7.7 months in the standard arm and 12.6 months in the HIPEC arm ($p = 0.02$). A 5-year survival of 45% was observed in patients in whom an R1 resection was possible. The authors concluded that CRS + HIPEC significantly adds survival time to patients with colorectal peritoneal carcinomatosis. The results of other contemporary series are presented in Table 4 [161–165].

It should be appreciated that CRS + HIPEC is a major surgical undertaking requiring the expertise of a specialized team. Even in the best of centers the procedure is associated with morbidity rates of 30–40%, readmission rates of 11%, reoperation rates of 10%, and a mortality rate of 2% [166]. However, with many studies presenting a median survival of 30–40 months, CRS + HIPEC should be offered to a select group of patients with colorectal peritoneal carcinomatosis, at centers with the desired expertise after in-depth counseling regarding the nature of the procedure, the associated morbidity, and the expected results.

8 Medical Management

Surgery is the first line of management for resectable colon cancer. The role of chemotherapy is largely restricted to the adjuvant and metastatic setting. Neo-adjuvant chemotherapy (NACT) for locally advanced T4b colonic primaries with frank adjacent organ infiltration has not been adequately explored. Only two studies have been reported until now for NACT in locally advanced colon cancer i.e. a pilot study [167] and a phase II study [168]. Both these studies have confirmed the feasibility, acceptable toxicity, and perioperative morbidity and have shown initial results of tumor downstaging, fewer incomplete resections, reduced apical lymph node metastasis [167], and a possible benefit of avoiding adjuvant chemotherapy, in patients with good response [168]. However, until further evidence is available, the role of chemotherapy in colon cancer is largely restricted to the adjuvant and metastatic settings.

8.1 Role of Adjuvant Chemotherapy in Colon Cancer

The goal of adjuvant therapy is to address potential microscopic metastatic cancer cells after curative surgery, thereby decreasing local and distant recurrence and increasing overall survival (OS). Adjuvant therapy in colon cancer was first introduced into clinical practice in the early 1960s, soon after the anti-cancer efficacy of 5-FU was demonstrated.

Two main treatment regimens of bolus 5-FU plus leucovorin were in vogue in the mid-1990s; the Mayo regimen (daily bolus FU/leucovorin for 5 days every 4–5 weeks) and the Roswell Park regimen (weekly bolus FU/leucovorin for 4 weeks in a 6-week cycle); both were administered for 6 months. The Multicenter International Study of Oxaliplatin/5-FU/leucovorin in the Adjuvant Treatment of Colon Cancer trial (MOSAIC) has shown that in terms of 3-year DFS, oxaliplatin plus infusional 5-FU and LV (FOLFOX) is superior to 5-FU with LV [169].

The DFS benefit for FOLFOX compared with 5-FU and LV alone was approximately 3.5%.

in unselected patients, with stage II disease. However, it exceeded 5%, for patients with stage II tumors with high-risk features like undifferentiated tumors, T4, perforation, obstruction, fewer than 12 lymph nodes identified, and presence of angio-lymphatic invasion. An update of the MOSAIC trial has shown a significant improvement in 6-year OS for patients with stage III colon cancer. However, such benefit was not seen for patients with stage II colon cancer when an oxaliplatin-based regimen was used as adjuvant therapy [170].

The XELOXA trial (oxaliplatin/capecitabine [XELOX] vs. bolus 5-FU/LV), showed the role of oxaliplatin as an important component of adjuvant therapy in stage III colon cancer with significant improvements in DFS (HR, 0.80; 95% CI; 0.69–0.93; $p = 0.0045$) and a trend towards improved OS at 5 years [171]. Based on the results of the XELOXA trial, the standard adjuvant chemotherapy for stage III colon cancer is an oxaliplatin-based regimen (FOLFOX, XELOX, or bolus 5-FU/folinic acid/oxaliplatin [FLOX]) administered for 6 months.

To alleviate the long-term neurotoxic side effects of oxaliplatin-based adjuvant therapy, the International Duration Evaluation of Adjuvant chemotherapy (IDEA) collaboration was established to prospectively combine and analyze the data from six randomized trials conducted around the world to find the answer to the question that a 3-month course of oxaliplatin-based adjuvant therapy is non-inferior to the current standard 6-month treatment for patients with stage III colon cancer. Subgroup analyses suggested that 3 months of adjuvant therapy may be non-inferior for low-risk stage III colon cancer (e.g., pT1–3 N1); whereas for high-risk stage III diseases (T4 or N2+), 6 months of adjuvant oxaliplatin-based therapy is the standard of care [172].

The role of adjuvant chemotherapy remains controversial for patients with Stage II colon cancer. A trend towards improved recurrence-free survival and OS was demonstrated in the results of a series of clinical trials. Retrospective analyses of large adjuvant trials and pooled data sets have shown remarkably consistent results that patients with stage II disease and MSI-high tumors, which represent tumors of the deficient mismatch repair phenotype (d-MMR), have an excellent prognosis and do not require adjuvant chemotherapy [173–175]. The development of a molecular profile of prognostic variables that could potentially guide adjuvant treatment decisions in stage II colon cancer is underway [174]. Gene expression signatures such as the Oncotype DX Colon and ColoPrint are included in these tests [176].

The role of novel targeted agents, such as Bevacizumab (an anti-VEGF) and Cetuximab (an anti-EGFR) has been investigated in the adjuvant setting in ongoing large phase II trials of advanced colorectal cancers. Bevacizumab and Cetuximab are not recommended in the adjuvant therapy of colon cancer outside of clinical trials, as of now. For early-stage colon cancer, randomized trials are on the way to evaluate the role of aspirin and celecoxib as adjunctive therapy with standard surgery and adjuvant chemotherapy.

In summary, for stage III colon cancer, adjuvant chemotherapy with an oxaliplatin-based regimen is the standard of care. Due to the marginal benefit in some subgroups, the role of adjuvant therapy in stage II colon cancer should involve shared decision-making. After completion of adjuvant therapy, important aspects like lifestyle changes, diet, exercise, and the use of anti-inflammatory agents must be discussed with the patients.

8.2 Role of Chemotherapy in Metastatic Colorectal Cancer

The prognosis for stage IV disease without therapy is usually poor with a median survival of 5–6 months. The addition of Oxaliplatin/Irinotecan to 5-FU/LV resulted in an improvement in median survival to around 24 months. Until 2000, the standard first-line therapy for metastatic colon cancer was 5-FU/LV as a bio-modulator and activator. Later on, Oxaliplatin/Irinotecan along with 5FU + LV have been investigated in many trials.FOLFOX, CAPEOX, and FOLFIRI regimens are FDA approved standard-of-care regimens, for first-line treatment in the metastatic setting.

The introduction of biological agents, such as bevacizumab, cetuximab, and panitumumab, has enhanced the efficacy of systemic therapy. These biological agents block one of two receptor sites viz. the VEGF (vascular endothelial growth factor) or the EGFR (epidermal growth factor receptor). Bevacizumab, Ramucirumab and Ziv-aflibercept block VEGF. The addition of Bevacizumab has shown clinical efficacy in several trials for the treatment of metastatic colorectal cancer in terms of response rates, PFS and OS in the first-line setting. Ramucirumab is a human monoclonal antibody directed against the VEGF receptor-2. Along with FOLFIRI it has been evaluated as a second-line therapy for patients, pre-treated with a fluoropyrimidine plus oxaliplatin and bevacizumab, and has shown improved OS (median OS, 13.3 months vs. 11.7 months; HR, 0.8; 95% CI; 0.73, 0.98; $p = 0.022$) and PFS [177]. Ziv-aflibercept (VEGF-Trap) was tested as a second-line treatment in a trial among patients who had all failed oxaliplatin-based first-line chemotherapy with favorable results [178].

Anti-EGFR antibodies, Cetuximab and Panitumumab have been tested as components of first-line therapy in combination with chemotherapy regimens, such as FOLFOX and FOLFIRI. It is now evident that patients with metastatic colorectal cancer must have a tumor that is wild type (i.e., non-mutated) for both K-RAS and N-RAS for these EGFR antibodies to be effective [179, 180]. There are no data to support a switch from one EGFR antibody to the other in the case of tumor progression, however, panitumumab can be considered for patients with allergic reactions to cetuximab. Currently, no difference is evident in outcome between first-line chemotherapy with bevacizumab or cetuximab. So, the treatment approach can be adjusted depending on patient and physician preference, the aim of therapy, the side-effect profile, and the cost of the therapy.

BRAF V600E (i.e., Valine(V) substituted for glutamate(E) at codon 600) mutations are found in about 5% to 10% of patients with colorectal cancer. BRAF mutations are usually, mutually exclusive with RAS mutations and are consistently associated with poor prognosis [181, 182]. The median survival of patients with BRAF-mutated stage IV colorectal cancer is 12–14 months [181]. Recent data suggests that an aggressive first-line treatment approach, with a triplet chemotherapy combination (FOLFOXIRI) plus bevacizumab might counteract the poor prognosis of this tumor genotype, to some extent [183, 184].

Regorafenib, a tyrosine kinase inhibitor that blocks the VEGF receptor, has been approved as salvage therapy in patients with metastatic colorectal cancer who have previously been treated with a 5-FU, oxaliplatin, irinotecan, and Cetuximab/Panitumumab [185].

Immune checkpoint inhibitors targeting the PD-1 pathway by binding to PD-1 or its ligand (PD-L1/L2) have shown efficacy in metastatic colorectal cancer. MSI-H/dMMR colon cancers are commonly characterized by dense lymphocytic infiltrates, which indicates a potential activation of the host's immune system [186, 187]. Based on these observations, a pilot study was initiated to investigate the role of Pembrolizumab, an antibody against PD-1, in heavily pre-treated patients with advanced colorectal cancer, classified by their MSI status. Monotherapy with Pembrolizumab showed remarkable activity, only in patients with MSI-H/dMMR cancers independent of their histology. So it is approved for MSI-H/dMMR tumors following prior treatment with a 5-FU, oxaliplatin, and irinotecan [188]. A subgroup of BRAF mutant colorectal cancer is dMMR and, therefore, a candidate for immunotherapy.

NACT can be used to downsize unresectable metastases to make them amenable to surgery. It has been shown that the OS of patients, who undergo successful NACT with subsequent R0 resection of liver metastases, is almost similar to the survival of patients with initially resectable metastases [189, 190].

To summarize, patients with stage IV disease have a chance of cure if an R0 resection is feasible at all metastatic sites. Various cytotoxic drugs (fluoropyrimidines, oxaliplatin, and irinotecan) and targeted agents (bevacizumab, aflibercept, regorafenib, as well as cetuximab and panitumumab in RAS wild-type cancers) have shown proof of efficacy for metastatic colorectal cancer. Expanded RAS mutation testing for mutations in KRAS and NRAS is mandatory before the use of EGFR monoclonal antibodies. There is no single standard of care first-line regimen for the management of metastatic colon cancer. Group decision-making is required which involves molecular and histologic assessment of the tumor, aim of the treatment, anticipated toxicity, and cost of therapy.

9 Radiation Management

The role of radiotherapy in colon cancer is very limited. Adjuvant radiotherapy is only recommended for tumors with positive or close retroperitoneal margins. This is only relevant in the caecum/ascending or descending colon, in tumors with posterior infiltration into the retroperitoneal structures where an R0 resection has not been achieved.

Palliative radiotherapy has a role in symptomatic bony metastasis, and unresectable, bleeding tumors.

10 Stage-Wise Management Algorithm

Stage I (T1/T2, N0, M0)—Radical colectomy → surveillance.

Stage II (T3/T4, N0, M0)—Radical colectomy → may consider adjuvant chemotherapy in high-risk stage II (i.e., poorly differentiated tumour (without MSI—H), obstruction, perforation, lymph node yield<12, lymphovascular invasion, perineural invasion) → surveillance.

Stage III (T1–4, N1–2, M0)—Radical colectomy → 6 months of adjuvant chemotherapy (5FU + Oxaliplatin) → surveillance.

Stage IV (Any T, Any N, M1)—Multidisciplinary management (refer to Sect. 12).

11 Stage-Wise Prognosis with Current Treatment

Stage	5-year survival rates [191] (%)
Stage I	92
Stage IIA	87
Stage IIB	65
Stage IIIA	90
Stage IIIB	72
Stage IIIC	53
Stage IV	12

12 Management of Recurrent Disease Including Specific Palliative Measures

Recurrent disease following radical colonic resection with or without adjuvant chemotherapy may be local or systemic. Metachronous distant metastasis is managed according to the principles of management for stage IV disease i.e. systemic chemotherapy with surgical resection if an R0 resection is feasible at all metastatic sites. Local recurrence may be nodal (most often at the root of the draining vascular pedicles of the resected primary) or luminal or both. Although systemic chemotherapy is essential in most cases of local recurrence, the best long-term outcomes are achieved only in cases where an R0 resection of the recurrent disease is achieved. Luminal recurrences can sometimes be resected R0 with multivisceral resections but large nodal recurrences at the root of the superior mesenteric artery are largely unresectable.

Bowel obstruction and intraluminal bleeding are probably the two most common presentations of recurrent colon cancer. For unresectable lesions, a diversion ileostomy or intestinal bypass offers good palliation of intestinal obstruction. However, in the presence of associated peritoneal disease, a careful evaluation of the level of obstruction and the number of points of obstruction is prudent before surgical exploration. Extensive peritoneal disease with an infiltrated small bowel mesentery and multi-level small bowel obstruction is generally not amenable to surgical palliation. Palliative radiotherapy plays an important role in symptomatic bone metastasis and may help decrease bleeding from unresectable lesions.

When determining if adjuvant therapy should be administered, the following should be taken into consideration:

- Number of lymph nodes analyzed after surgery (<12)

Fig. 5 (continued)

- Poor prognostic features (eg, poorly differentiated histology [exclusive of those that are MSI-H]; lymphatic/vascular invasion; bowelobstruction; PNI; localized perforation; close, indeterminate, or positive margins)
- Assessment of other comorbidities and anticipated life expectancy.
- The benefit of adjuvant chemotherapy does not improve survival by more than 5%

Special situations: (MDT DECISION)

- Locally advanced colon cancer ,unresectable or requires multivisceral resection:
- Consider 6 weeks for NACT : CAPOX 2 #/ FOLFOX 3 # (FOXTROT TRIAL)

Small Intestine Cancer

Vikram A. Chaudhari, Parag R. Ingle, Manish S. Bhandare,
and Shailesh V. Shrikhande

Abbreviations

CAPOX	Capecitabine and oxaliplatin
DBE	Double balloon enteroscopy
EGD	Esophagogastroduodenoscopy
EGFR	Epidermal growth factor receptor
EUS	Endoscopic ultrasonography
FAP	Familial adenomatous polyposis
FU	Fluorouracil
GIST	Gastrointestinal stromal tumor
HNPCC	Hereditary nonpolyposis colorectal cancer
MMR	Mismatch repair
NCDB	National Cancer Database
NET	Neuroendocrine tumor
OS	Overall survival
PD	Pancreatoduodenectomy
SIA	Small intestinal adenocarcinoma
SIC	Small intestine cancer
TNM	Tumor, node, metastasis
VEGF	Vascular endothelial growth factor

1 Introduction

Small intestine contributes to 75% of the length of the gastrointestinal tract and 90% of its mucosal area; however, small intestine cancer (SIC) forms a small share (3%) of the entire gamut of gastrointestinal tract cancers [1]. Rarity of cancer development at this site can provide insights into presence of possible preventive mechanisms in this organ and anticancer strategies for more common malignancies at other sites. Adenocarcinoma of the small intestine is a rare malignancy. It is frequently diagnosed at advanced stage with either nodal or distant metastasis.

2 Epidemiology

Incidence of SICs in India appears to be extremely low, and no epidemiological studies have been published. Hospital-based data from India suggest that lymphomas of small bowel are more common than carcinomas [2]. Global incidence of SIC is less than 1.0 per 100,000 population [3]. Approximately 10,470 patients are diagnosed with and 1450 succumb to SIC every year in the United States [1, 4]. It accounts for only 0.42% of total cancer cases and 2.3% of cancers of digestive system in the United States. It is more common in North America and Europe than Asia [5]. SIC is usually seen in the sixth and seventh decades of life [2]. SIC is more common in men compared to women [4].

3 Histology

More than 40 histological types of small bowel tumors are known [6]. Adenocarcinoma (36.9%), carcinoid (37.4%), lymphoma (17.3%) and gastrointestinal stromal tumor (GIST) (8.4%) are four commonly found primary small bowel tumors (Table 1) [7]. Adenocarcinomas are seen more frequently in duodenum; NETs often develop in ileum while lymphomas tend to occur in jejunum. In the past few decades, incidence of small bowel neuroendocrine tumor (NET) has surpassed that of adenocarcinomas of small bowel [8, 9]. Benign tumors such as adenomas, lipomas and hemangiomas also occur in the small bowel. The focus of this chapter is on management of small intestinal adenocarcinoma (SIA).

Table 1 A few important histological types of small intestinal tumors (WHO classification) [5]

Epithelial tumors **Adenoma** **Intraepithelial neoplasia (dysplasia)**
Carcinoma • Adenocarcinoma • Mucinous adenocarcinoma • Signet-ring cell carcinoma • Small cell carcinoma
Carcinoid (well-differentiated endocrine neoplasm) **Nonepithelial tumors** • Lipoma • Leiomyoma • Gastrointestinal stromal tumor • Leiomyosarcoma
Malignant lymphomas **Metastasis** **Polyps** • Hyperplastic (metaplastic) • Peutz–Jeghers

4 Etiopathogenesis

Faster transit time compared to colon and rectum, relatively diluted liquid contents, higher amount of lymphoid tissue in small intestinal wall and rapid turnover of cells are few hypotheses proposed to explain low incidence of cancer at this site. Various risk factors and predisposing conditions are known to be responsible for causation of SIC. Many SIAs develop from adenomas through adenoma–carcinoma multistep sequence involving multiple specific genetic changes at each step, similar to colorectal adenocarcinoma [10]. Size and histology of the adenomas influence the risk of progression to adenocarcinoma. Larger size and villous adenomas carry higher risk for progression. Molecular biology of SIA and colorectal adenocarcinomas shows similarity [11]. DNA mismatch repair (MMR) pathway alterations are also frequently found in SIAs similar to colorectal adenocarcinomas. A high percentage of SIAs also exhibit epidermal growth factor receptors (EGFR) and vascular endothelial growth factor (VEGF) receptors, suggesting that therapeutic strategies targeting them may be useful in SIAs [12].

4.1 Hereditary Cancer Syndromes, Predisposing Conditions and SIA [13] (Table 2)

4.1.1 Hereditary Nonpolyposis Colorectal Cancer (HNPCC) Syndrome

Germline mutations in DNA mismatch repair genes are responsible for causation of HNPCC. Patients have increased risk of developing colorectal cancer as well as cancers of other organs like small intestine and endometrium. The risk for SIA has been reported to be higher in MLH1 mutation carriers [90]. HNPCC-associated SIAs occur at an earlier age and appear to have a better prognosis than those occurring in the general population [14].

Table 2 Risk factors for small intestine cancer

Hereditary syndromes • HNPCC (hereditary nonpolyposis cancer colon syndrome) • Familial adenomatous polyposis • Peutz–Jeghers syndrome • Cystic fibrosis
Inflammatory conditions • Crohn's disease • HIV infection • Coeliac disease **Lifestyle-related factors** • Tobacco usage • Smoking • High intake of red meat and smoked food **Previous surgery-related factors** • Ileostomy • Pouches • Conduits • Biliary diversion

4.1.2 Peutz–Jeghers Syndrome

The syndrome is characterized by hamartomatous polyps in gastrointestinal tract. Patients with Peutz–Jeghers syndrome are at increased risk of small bowel, other gastrointestinal, breast, ovarian, uterine cervical, ovarian, testicular and lung cancers [15].

4.1.3 Familial Adenomatous Polyposis (FAP) Syndrome

FAP syndrome is caused by germline mutation in APC gene. Patients develop colonic and duodenal adenomatous polyps and have increased risk of adenocarcinoma development. Fifty to 90% of patients with FAP develop duodenal adenomatosis, and 3–5% of these patients develop duodenal cancer. Risk of malignant transformation is higher with periampullary adenomas [16, 17].

4.2 Inflammatory Bowel Disease and Chronic Inflammation

Small intestinal Crohn's disease predisposes to adenocarcinoma. Relative risk is reported to be as high as 60. Extended duration of the disease, distal jejunal and ileal location, male sex, small bowel bypass loops, strictures, chronic fistulous disease, young age at diagnosis and occupational hazards (aromatic compounds, asbestos and solvents) are suggested to be associated with an increased risk of small bowel carcinoma in patients with Crohn's disease [13]. There is a proportionate increase in risk with increase in extent as well as duration of small bowel involvement. Celiac disease is an inflammatory small intestinal disorder characterized by the inability of the small intestine to deal with the gluten fractions of cereals. Celiac disease increases risk of SIA as well as small bowel lymphoma. Similar to Crohn's disease, relative risk is reported to be as high as 60 to 80. SIAs associated with celiac disease are most often located in the jejunum and are more likely to develop as an adenoma–carcinoma sequence than as dysplasia in flat mucosa [18].

4.3 Other Associations

Radiation exposure and cystic fibrosis also seem to be involved in causation in some cases.

Tobacco usage, smoking, high intake of red meat and smoked food are associated with SIA [19]. Ileostomy, pouches, conduits and biliary diversion increase the risk of SIA [20].

5 Clinical Presentation

In early stages, adenocarcinoma of the small intestine is usually asymptomatic. Most patients present with symptomatic lesions during the sixth and seventh decades of life. Age of presentation is usually 10 years earlier than average age for sporadic cases and for tumors arising in individuals with genetic or familial predisposition [14, 21]. Symptoms are vague which results in late of detection of these cancers. Symptoms may include nausea, vomiting, abdominal pain, constipation, malaise, weight loss, anemia and diarrhea. Usually patients develop symptoms when tumor grows large and obstructs the small intestine or compresses on adjacent structures. Approximately 77% of small bowel cancers present with intestinal obstruction or peritonitis due to bowel perforation [14]. Occult blood in stools or hematochezia can be the manifestations of SIC. Few small intestinal tumors may be detected incidentally or may present as an innocuous primary with distant visceral metastasis especially in case of neuroendocrine tumors (NET).

6 Evaluation and Work-Up

Long length and anatomy of small intestine make diagnosis of small bowel neoplasms difficult and challenging. Small intestinal cancer distal to the duodenum is relatively inaccessible. Definitive preoperative diagnosis is made in up to 30–40% patients.

Esophagogastroduodenoscopy (EGD) is useful in identifying and sampling duodenal lesions. Push and pull enteroscopy (double balloon enteroscopy) and capsule endoscopy are two diagnostic tools with potential to locate the site of primary in jejunum or ileum. The accuracy rates of double balloon enteroscopy (DBE) ranges from 94% to 100% depending on the histology [22]. Push–pull enteroscopy has capability of therapeutic intervention but also needs greater expertise and anesthesia [23].

CT scan and MRI usually help to locate distant and nodal metastasis but have a low sensitivity to identify the primary. The benefit of CT scan over conventional imaging methods of small bowel enteroclysis or barium small bowel follow through is demonstration of both intraluminal as well extraluminal features related to the tumor. Duodenal lesions are usually seen as intraluminal polypoidal lesions on cross-sectional imaging while distal polypoidal lesions may cause intussusception and generate a characteristic "target sign." Adenocarcinomas are seen as tumor mass with annular luminal narrowing and irregular edges. CT enteroclysis with high volume neutral oral contrast or direct infusion of contrast into the small bowel helps in improving sensitivity of tumor localization [24].

7 Staging

Small intestine cancer is staged as per the AJCC—tumor, node, metastasis (TNM) cancer staging system. Depth of tumor invasion determines the T stage where T1 refers to tumor infiltration up to submucosa and T4 implies adjacent organ infiltration. Stage groupings are similar to colonic cancer staging. Node-negative T1, T2 disease implies Stage 1, and T3, T4 is a stage II disease. Node-positive disease determines Stage III, and distant metastasis is a stage IV disease [25].

8 Management

8.1 Surgical Management of SIA

Management usually is dictated by the histology of the neoplasm. Resection is definitive treatment for most small bowel neoplasms. Surgery involves excision of tumor with at least 5 cm margins on each side of the bowel and mesentery to clear the draining lymph nodes till the base of supplying mesenteric vessel. Simple excision suffices for benign tumors of small intestine.

8.1.1 Duodenal Adenocarcinomas

Duodenal adenocarcinomas involving the ampulla usually warrant a pancreatoduodenectomy (PD) for radical excision of the tumor. Ampullary resection, i.e., ampullectomy, may suffice for ampullary adenomas or early ampullary adenocarcinomas. Ampullectomy can be considered in benign lesions smaller than 3 cm, small neuroendocrine tumors and T1 well-differentiated carcinomas of the ampulla [26, 27].

Ampullary resections can be accomplished by endoscopy guidance or transduodenal surgical approach [28, 29]. Clinical judgment, endoscopic ultrasonography (EUS) and intraoperative pathological confirmation are helpful in determining adequacy of resection [19]. It has been noticed that tumor with characteristics of protruded adenoma or well-differentiated adenocarcinoma, no duodenal invasion as determined by endoscopic ultrasonography, no pancreatic ductal infiltration as determined by intraductal ultrasound and diameter of the pancreatic duct ≤3 mm determined by endoscopic retrograde cholangiopancreatography had no lymph node metastasis [30]. Such tumors seem to be ideal candidates for curative ampullary resection. Compliance to surveillance protocol is important and a must after ampullary resection as it is associated with higher rate of recurrence [31, 32]. Pancreas preserving duodenectomy with lateral duodenojejunostomy may be required for lesions of third and fourth parts of duodenum [33]. Some superficial nonampullary duodenal tumors (localized to mucosa and submucosa), which are not feasible for endoscopic resection, may be amenable to transduodenal excision and local full thickness resection. This can also be accomplished by minimally invasive technique with combination of laparoscopy and endoscopy in selected cases [34]. These surgical modalities help to obviate the need of PD or pancreas preserving duodenectomy. This should be attempted in clinicoradiologically node-negative cases or in patients with low risk of nodal metastasis [26]. PD does not confer survival advantage compared with segmental resection as per various retrospective studies [35, 36]. A large series from Mayo clinic did not demonstrate any statistically significant difference in terms of 5-year overall survival (OS), rate of R0 resection or local recurrence between pancreatoduodenectomy or total pancreatectomy versus segmental resection or transduodenal excision of duodenal tumors [37]. There was no significant difference between the two groups in terms of 5-year overall survival (52% vs. 61%), rate of margin negative resections or local recurrence rates.

8.1.2 Jejunal and Ileal Adenocarcinomas

Patients with these lesions may present with intestinal obstruction or melena necessitating emergency surgery. Optimization of these patients before embarking on surgery should be performed. En bloc resection of involved segment and mesentery with adequate margins is needed. Terminal ileal lesions may necessitate a radical right hemicolectomy.

8.2 Adjuvant Chemotherapy for Small Bowel Adenocarcinomas

There is a dearth of prospective trials evaluating the role of adjuvant chemotherapy post resection of SIAs. Evidence for adjuvant chemotherapy for small intestinal adenocarcinomas exists in the form of retrospective studies and is mainly 5-fluorouracil based.

Regimen containing oxaliplatin plus short-term infusional fluorouracil (FU) and leucovorin is usually selected based on the MOSAIC trial that proved it to be superior to FU and leucovorin alone in patients with colon cancer [38]. Survival advantage with adjuvant chemotherapy compared to surgery alone was seen in a propensity score-matched analysis of data from the National Cancer Database (NCDB) [39]. Use of adjuvant chemotherapy in small bowel adenocarcinoma is based upon the patterns of recurrence and an extrapolation from evidence showing its survival benefit in node-positive colon cancer cases.

8.3 Management of Metastatic Disease

Role of surgery in metastatic disease is mainly to palliate bleeding, obstruction or perforation. Resection may be warranted in case of bleeding or perforation in primary tumors. Intestinal bypass surgery may be helpful to maintain oral intake of food and improve symptoms and quality of life in patients with obstructed primaries. Mainstay of treatment in this scenario is palliative chemotherapy. Palliative chemotherapy compared to best supportive care provided a survival benefit in multiple retrospective studies [40]. The various regimens being studied in phase II trials include combination of capecitabine and oxaliplatin (CAPOX) with bevacizumab, CAPOX with panitumumab and Nab-paclitaxel [41].

9 Prognosis

As majority of cases are diagnosed in advanced stage, prognosis is usually poor. Five-year disease-specific survival was 65% for stage I, 48% for stage II, 35% for stage III and 4% for stage IV disease [34]. Poor prognostic features include old age (>55 years), T4 tumor, lymph node involvement, duodenal followed by ileal primary and positive margins [42, 43].

10 How We Do It at TMC (Table 3)

In our experience, oncologic small bowel resections were more commonly performed for lymphomas and non-SIA pathologies in TMC than for adenocarcinomas.

A multidisciplinary team consisting of surgical oncologist, medical oncologist, radiotherapist, pathologist, radiologist, interventional radiologist and palliative care specialists is involved in treatment planning in elective presentations. High-risk patients are discussed with the team of anesthesi-

Table 3 Summary

- SIAs are rare and comprise approximately one-third of small intestinal malignancies.
- Hereditary cancer syndromes, chronic inflammatory conditions of the bowel and particular lifestyle-related factors are implicated in causation.
- Presentation is usually delayed and vague or sometimes acute due to complications of intestinal obstruction or melena.
- Diagnosis is usually by endoscopy for duodenal lesions and cross-sectional imaging for distal lesions.
- Radical resection is the only curative therapy.
- Adjuvant chemotherapy regimens are analogous to colon cancer.
- Obstruction, bleeding and/or perforation in advanced stages can be palliated by surgery.
- Palliative chemotherapy helps improve survival in metastatic disease.

ologist by surgical team before all major elective procedures, and decisions regarding adjuvant therapy are also planned in a similar multidisciplinary clinic. A personalized management plan is offered after taking into consideration the patient-related factors, disease-related factors and the logistics. The treatment plan is conveyed to and discussed with the patient and relatives after such clinic by the primary surgical team, and patients are guided to the appropriate specialists.

1 Introduction

Anal canal cancer is a rare gastrointestinal malignancy accounting for 1–6% of anorectal neoplasms [1]. Over the decades, the treatment for anal canal cancer has transitioned from surgery to sequential treatment (chemotherapy, chemoradiation, surgery) to definitive chemoradiation alone. Chemoradiation is the standard of care despite absence of randomized trials comparing it with surgery [2]. This is one of the few cancers which exemplify organ preservation achieved with definitive radiotherapy.

Anal canal is the distal part of the gastrointestinal tract and measures about 3–4 cm in length [3]. Dentate or pectinate line is an important landmark, where the glandular mucosa transitions to squamous mucosa. A zone of transitional epithelium may be present just proximal to dentate line. Anal canal extends from the anorectal ring (puborectalis muscle sling or 1–2 cm proximal to dentate line) to the anal verge. Anal verge is a mucocutaneous junction defined at the point at which the nonkeratinizing squamous epithelium lining the anal canal merges with the perianal skin. Other landmarks are outer edge of the internal anal sphincter and the palpable intersphincteric groove. The wall of anal canal is composed of internal and external sphincter muscles. The internal sphincter is the distal continuation of the inner circular muscular layer of rectum while the external sphincter is composed of levator ani, puborectalis sling and the external sphincter muscle. Anal canal is lined by three different histologies namely glandular and transitional in the proximal portion (above dentate line) and squamous in the distal portion [4]. Anal margin is a separate entity and is defined as the area extending up to 5 cm from the anal verge. Perianal cancers are defined as tumors that arise within the skin at or distal to the squamous mucocutaneous junction, can be seen entirely with gentle traction on the buttocks and are within 5 cm of the anus as per the American Joint Committee on Cancer (AJCC) eighth edition [5]. Dentate line acts as the watershed for lymphatic drainage. Tumors above the dentate line drain to mesorectal and internal iliac nodes while those below it, drain to the superficial and deep inguinal nodes and femoral nodes.

2 Incidence and Epidemiology in India and Global

Anal canal cancers account for 2% of all gastrointestinal cancers [1]. The age-standardized incidence rate of anal canal cancer is around 1 to 2 per 100,000 per year. The inci-

dence is rising worldwide over the years at the rate of 1–3% per year [6]. Islami et al. evaluated the international trends in anal canal cancer [7]. They noted an increase in incidence in mainly developed high-income countries, while in the Asian countries and Spain, the incidence was low and incidence remained unchanged. The reasons for the rise are related to sexual behavior, human immunodeficiency virus (HIV) infection, immunosuppression and high incidence and persistence of human papilloma virus (HPV) infection [8]. In the United States, about 8600 cases are diagnosed annually and account for 0.5% of all cancers [9].

In India, anal canal cancer is uncommon. Takiar et al. estimated the total number of cancer cases in India from 2010 to 2020 [10]. The estimated cases of anal canal cancer were 3500 in 2010, 3750 in 2015 and 4083 by 2020. There was higher incidence in males compared to female. As per GLOBOCAN 2018, anal canal cancers account for 0.5% of all new cases and 0.5% of mortality due to cancer. The total number of new cases amounts to 4895 with a cumulative risk of 0.04% [11].

2.1 Risk Factors

Historically, chronic inflammation due to hemorrhoids, fissure or inflammatory bowel disease was thought to be causative for anal canal cancer [12]. This has been disproved by various large cohort studies [13, 14]. The established risk factors for anal canal cancer are HPV, HIV, anal receptive intercourse, multiple sexual partners, exposure to sexually transmitted diseases, smoking, immunosuppression and prior history of preinvasive or invasive cervical, vaginal or vulval cancer. There is a higher preponderance among men. However, incidence among women is increasing due to HPV.

2.2 HPV

HPV is the most common sexually transmitted disease worldwide and is the main causative risk factor for anal cancer. A strong association has been seen between HPV and malignancies of cervix, vulva and anal canal. Over 90% of cases of anal canal cancer are associated with HPV and HPV DNA has been isolated from tissue [15]. The most common subtype seen in anal cancer is HPV 16 [16]. P16 is a surrogate marker for HPV 16 and can be readily identified on immunohistochemistry. HPV is also associated with precursor lesions and in men who have sex with men (MSM).

2.3 HIV

The HIV-positive individuals have two-fold higher risk of anal canal cancer especially among MSM [17]. Despite highly active antiretroviral therapy (HAART), the incidence has increased [18]. In HPV-positive individuals, coexistent HIV infection further increases the risk of precursor anal lesions and anal canal cancer and time afforded by treatment may allow these lesions to progress to malignancy [19]. The causative mechanism of HIV in anal canal cancer is not clear. It is plausible that HIV interacts with HPV leading to higher prevalence of HPV, HPV replication and persistence in HIV-infected individuals. Immunosuppression due to HIV may be contributory factor as well.

2.4 Sexual Activity

Receptive anal intercourse is a strong risk factor with a relative risk of over 30. The highest incidence is seen in MSM with HIV and HPV co infection [20]. Multiple sexual partners, history of genital warts, history of sexually transmitted disease like chlamydia trachomatis or gonorrhea are risk factor for anal cancer in both sexes [21]. A history of cervical dysplasia or cervical cancer also increases the risk for anal cancer possibly due to HPV infection [22].

2.5 Smoking

Smoking increases the risk of anal canal cancer (relative risk 2–5) and acts as a cocarcinogen for cervical cancer [23, 24].

2.6 Chronic Immunosuppression

Immunosuppression in patients with solid organ transplant and autoimmune disease (on steroids) is associated with high risk of anal canal cancer. This could be related to increased risk of HPV infection and persistence due to impaired ability of the body to clear HPV.

3 Clinical Presentation in India and Global

Anal canal cancer is commonly seen in older adults with a peak age of presentation between 60 and 65 years [25]. Women are more commonly affected. The diagnosis of anal canal cancer is often delayed as symptoms are commonly attributed to hemorrhoids or fissure in ano [26]. The most common symptom of presentation is bleeding per rectum which is seen in over 45–50% of the patients [25]. Other symptoms are pain, mass per rectum, mass in inguinal region (about 30%). The tumor may extend to the rectum or perianal skin. About 20% of patients may not have any symptom. A history of anal warts may be present in 30–50% of the cases. As per the SEER database, 50% have localized disease in the anus, 30% present with lymphadenopathy, 12% have metastatic disease and another 8% have unknown stage [27].

In India, men are more commonly affected than women [28]. Advanced disease at presentation is seen in over 45% of cases [29]. Patients present with large primary associated with ulceration, fungation, abscess or multiple fistulas in the perianal region. Invasion of rectovaginal septum in women and prostate or urethra in men may be seen in about 10%.

4 Evaluation and Work-Up

The clinical staging includes a detailed history and physical examination, pathological confirmation and imaging. A detailed digital rectal examination is a mandate and documentation of the craniocaudal extent, circumferential extent, involvement of rectum, anal sphincter tone should be done. A gynecological exam including cervical cancer screening is recommended. Clinical palpation of bilateral inguinal nodes should be performed, and fine needle aspiration of suspicious nodes should be done. Routine blood investigations (which includes complete blood picture, renal and liver functions tests) along with HIV testing should be carried out. In HIV-positive patients, CD4 count should be measured and HAART should be started.

Proctoscopy and biopsy with histological analysis are done to confirm the diagnosis. The most common histology is squamous cell carcinoma in over 80% [30]. Other histologies are basaloid, cloacogenic or transitional or adenosquamous [31]. Epidermoid carcinoma is a collective term used for all these histologies. Adenocarcinoma or melanoma is rare. Adenocarcinomas are managed as primary rectal cancers. The *Histological classification* of anal canal cancer is shown in Table 1.

Table 1 Histological classification

Histology
Squamous cell carcinoma • Large cell keratinizing • Nonkeratinizing (transitional) • Basaloid
Adenocarcinoma
Small cell carcinoma
Undifferentiated carcinoma
Others: • Sarcoma • Lymphoma • Melanoma

The extent of local and nodal disease is assessed by imaging. An accurate assessment of primary in terms of size and extent is required for staging. Magnetic resonance imaging (MRI) is the modality of choice to characterize the locoregional spread. The primary has low to intermediate signal relative to muscle on T1 weighted images and is hyperintense on T2 weighted images. The nodes have signal similar to primary. The tumor size, circumferential extent, invasion of adjacent organs (vagina, urethra, prostate and bladder), extension to ischioanal or ischiorectal fossa and presence of fistula should be documented. The sensitivity of MRI for local staging is 90–100% [32]. CT thorax and abdomen is usually performed to exclude distant metastases mainly in lung and liver. Distant metastasis at presentation is uncommon (9–20%). PET CT has shown encouraging results with upstaging of the disease in 17% of the cases and in 29% cases the management was altered [33]. Over 98% of anal cancers are FDG avid and PET has high sensitivity (89–98%). However, it is still considered investigational and not routinely practiced. It has a role in recurrent setting for staging especially when salvage surgery is planned. The routine follow-up posttreatment with PET-CT is not warranted [34]. The staging is performed with tumor node metastases (TNM) staging system and the eighth edition is currently used. The perianal cancers are staged and treated as anal canal cancer. Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 282, Chapter no. 21, Anus, Table: Definition of TNM and AJCC Prognostic Stage Groups which can be accessed at https://emedicine.medscape.com/article/2003634-overview

5 Principles of Management

Multimodality treatment approach is standard. Definitive radiation is the standard treatment for all stages. Chemotherapy is used in locally advanced cases along with radiation while in metastatic scenario, it is the sole treatment. Surgery is reserved for salvage post radiation and in early anal margin cancers.

5.1 Radiation Management

5.1.1 Evidence

Radiation is the principal modality of treatment in localized anal canal cancer due to its sphincter preserving and colostomy avoiding potential with superior oncological results. Nigro et al. were the first to explore chemoradiation in anal canal cancer with the intention of improving control rates with surgery alone [35]. Since squamous cell cancers are sensitive to radiation and chemotherapy acts as a radiosensitizer, the addition of chemoradiation prior to surgery was tested. The original Nigro's protocol consisted of a low dose of radiation (30 Gy in 15 fractions over 3 weeks) along with Mitomycin 0.5 mg/kg on day 1 and 5 Fluorouracil (5-FU) 25 mg/kg day 1–5 continuous infusion. The preliminary report of this regimen in three patients published in 1974 showed a complete clinical response (CR) in all three patients and a pathological CR in two patients (1 patient refused surgery) [35]. In an updated series of 45 patients, Leichman showed that 84% (*n* = 34) of patients had CR with chemoradiation alone and surgery was deemed unnecessary in this cohort [36]. Surgery was done only in case of residual tumor. The 5-year overall survival was 67%, and colostomy-free survival was 59%. This paved the way for practice change leading to acceptance of chemoradiation as the standard treatment even in the absence of a prospective randomized trial comparing surgery with chemoradiation.

These reports were further evaluated and confirmed by other investigators at different institutions with radical radiation doses (40–60 Gy) and different schedules (continuous and split course) [37–40]. Some studies showed good local control rates and survival outcomes with radiotherapy alone [41, 42]. The need for concurrent chemotherapy was questioned and there were concerns regarding increase in acute and late toxicity with concurrent chemotherapy.

Two large randomized controlled trials (RCT) compared radiation alone with chemoradiation. The United Kingdom Coordinating Committee for Cancer Research (UKCCCR) conducted a multicentric RCT in 585 patients of ACC (anal cancer trial ACT I) T1–T4 stage from 1987 to 1994 comparing 290 patients treated with radiation alone with 295 patients treated with combined modality treatment (CMT) [43]. Radiotherapy (RT) was delivered to a dose of 45 Gy in 20 to 25 fractions over 5 weeks in both arms. Chemotherapy consisted of 5FU (1000 mg/m^2 over 4 days or 750 mg/m^2 over 5 days in week 1 and 5 of radiation) and mitomycin (12 mg/m^2 bolus on day 1, single dose) in CMT arm. Response assessment was done at 6 weeks after treatment. Further radiotherapy boost (brachytherapy 25 Gy with iridium implant or external beam boost of 15 Gy/6 fractions) was considered in patients with good response (≥ 50% regression), while salvage surgery was done in poor responders. Local failure rate was the primary endpoint of the trial. At a median follow-up of 42 months, the CMT arm had significantly lower failure rates compared to RT alone (36% vs. 59%, $p < 0.0001$) with a 46% risk reduction. Overall survival was similar in both arms; however, deaths from ACC were reduced in CMT arm ($p = 0.02$). Acute toxicity was higher in CMT arm ($p = 0.03$).

A 13-year update from ACT 1 trial showed 25% reduction in risk of locoregional failure with CMT (32% vs. 54%, $p = < 0.01$) [44]. There was 12.5% reduction in risk of death from ACC in CMT arm. Median survival was 7.6 years with CMT vs. 5.4 years with RT alone. Noncancer deaths were higher in CMT arm and were predominantly due to cardiovascular cause, treatment related or pulmonary in first 5 years while due to secondary malignancy beyond 5 years. Lung cancer was the most common second malignancy, likely due to common risk factor of smoking. Early increase in noncancer deaths in CMT arm could be the reason for lack of survival advantage.

European Organization for Research and Treatment of Cancer (EORTC) conducted a RCT in 110 T2–T4 N0–3 or T1–2 N+ ACC patients from 1987 to 1994 comparing RT alone with CMT [45]. RT was delivered to a dose of 45 Gy in 25 fractions over 5 weeks in both arms. Chemotherapy consisted of 5FU (750 mg/m^2 over 5 days in weeks 1 and 5 of radiation) and mitomycin (15 mg/m^2 bolus on day 1, single dose) in CMT arm. Response assessment was done at 6 weeks after treatment. Boost of 15 Gy was given good responders while 20 Gy in poor responders. Surgery was done in case of stable disease or progression. Clinical CR was increased in CMT (80%). At 5 years, there was significant improvement in locoregional control rate by 18% ($p = 0.02$), colostomy-free survival by 32% ($p = 0.002$) and event-free survival ($p = 0.03$) with CMT. No difference in toxicities and overall survival between the arms.

These two trials have established chemoradiation as standard of care in localized ACC. Though there was no survival advantage, locoregional rates were superior with chemoradiation albeit with higher toxicity.

Conformal external beam radiotherapy should be used to get good target coverage and avoid the organ at risk. Intensity-modulated radiotherapy (IMRT) is preferred modality of treatment technique. Kachnic et al. evaluated the role of dose painted IMRT in anal canal cancers with the aim of reducing acute grade 2 or higher combined gastrointestinal and genitourinary toxicity (RTOG 0529) [46]. They showed significant reduction in acute grade 2+ hematologic and grade 3+ dermatologic and gastrointestinal toxicity. However, the primary endpoint was not met. On a follow-up of 8 years, the update by Kachnic et al. showed that the late effects were mainly grade 2–3 and lower compared to previous series (18% grade 1, 55% grade 2, 16% grade 3, 0% grade 4, 2% grade 5 (sinus bradycardia)) [47]. The outcomes were similar to historical cohort of RTOG 9811 with 5-year locoregional failure of 16%, disease-free survival (DFS) 68% and OS 76%.

5.2 Radiation Planning

The patients are positioned in supine position. To minimize skin folds, immobilization of legs in frog-leg position can be done. Markers should be placed at anal verge and on palpable or biopsy-proven adenopathy to avoid the risk of geographic miss. The target volumes include the gross disease (primary and nodes), a margin of 2–2.5 cm around the primary, entire mesorectum with perirectal lymph nodes and the elective lymph node volumes (bilateral inguinal, internal iliac and external iliac). The total dose prescribed varies according stage. T1–2 N0 tumors are treated to a dose of 50.4 Gy in 28 fractions at 1.8 Gy per fraction. T3–4 require a higher dose to about 54 Gy in 30 fractions at 1.8 Gy per fraction. Positive nodes are boosted to 54–55 Gy. In case of poor response at the completion of External Beam Radiotherapy (EBRT), further 5–10 Gy boost may be considered with either external beam or brachytherapy [28].

In case of metastatic setting, poor performance status or elderly (not fit for chemotherapy), shorter hypo fractionated schedules (40 Gy/15 fractions, 30 Gy/10 fractions or 20 Gy/5 fractions) may be considered for symptom and local control.

5.3 Response Assessment

Response to chemoradiation is assessed at 6–8 weeks after chemoradiation. If there is partial response or stable disease, patients are kept on follow-up till 6 months after completion of treatment [48]. If there is any progression posttreatment or up to 6 months, patients should be considered for biopsy. MRI is done to evaluate local extent of disease and suitability for surgical salvage. CECT thorax abdomen or Positron Emission Tomography-Computed Tomography scan (PET-CT) is done to rule out distant metastases. Biopsy is contraindicated in case of complete response. Biopsy of the irradiated tissues may lead persistent nonhealing ulceration due to poor vascularity and may lead to necrosis. Biopsy should be done only in the case of strong clinical suspicion of recurrence (proliferative growth or ulceration). If proven positive, MRI pelvis for local disease extent and CECT thorax abdomen or PET-CT should be done to rule out distant metastases.

5.4 Follow-Up

Follow-up is essentially clinical. Patients are followed up every 3 months for up to 2 years and every 6 months for up to 5 years and annually thereafter. At each visit, a clinical examination which includes digital rectal examination and palpation of bilateral inguinal nodal regions should be done. Fibrosis and stenosis of anal canal post radiation may preclude complete clinical examination. Imaging with MRI may be considered to detect local recurrences. Majority of the recurrences are locoregional and occur within 2 years. Long-term update of ACT-1 trial showed that beyond 5 years less than 2% of patients develop a locoregional relapse [44]. Distant metastases alone (without locoregional relapse) occurred in only 7%. Hence during follow-up, attention should be paid to detect early recurrences and complications of chemoradiation.

5.5 Complications

The most common acute complications are dermatitis, gastrointestinal (diarrhea and stomatitis), hematologic (anemia, leucopenia) and genitourinary. With IMRT the toxicity is less. The rates of acute toxicity were grade 2+ hematologic, 73%; grade 3+ gastrointestinal, 21%; and grade 3+ dermatologic, 23%. The late complications are diarrhea, proctitis and rarely anal stricture or incontinence. With IMRT the risk of late toxicity grade 3 and higher is 16%.

6 Chemotherapy Management

6.1 Evidence

6.1.1 Nonmetastatic Disease

Chemotherapy plays an important role in multimodality treatment. Although their concurrent role is well established, neoadjuvant and maintenance chemotherapy failed to show any benefit.

6.1.2 Concurrent Chemotherapy

The two RCTs (EORTC and UKCCCR ACT-1 trials) have shown the superiority of chemoradiation. The better local control and colostomy-free survival came at the cost of higher acute toxicity in the form of moist desquamation, diarrhea and hematologic toxicity. The overall acute toxicity in CMT arm of ACT-1 trial was 47% (140/292) compared to 39% with RT alone [43]. Severe skin, gastrointestinal and genitourinary reactions were seen in 35%, 10% and 2%, respectively, in CMT arm. Considering the toxicity profile of Mitomycin C, its efficacy and role in CMT was questioned. Nonrandomized studies showed improved outcome with addition of mitomycin compared to 5FU alone [49]. This was addressed by a randomized trial conducted by Flam et al. [50]. The Radiation Therapy Oncology group (RTOG) 8704 compared the addition of Mitomycisn to 5FU versus 5FU alone along with radiation in 310 patients of ACC. Radiation dose in both arms was 45 Gy in 25 fractions with boost up to 50.4 Gy to primary and positive nodes. 5FU was in both arms was administered at 1000 mg/m^2 continuous infusion for 4 days on day 1 and day 28 of RT. Mitomycin was administered at 10 mg/m^2 bolus on day 1 and day 28 of RT. Response assessment was done at 4 to 6 weeks after RT and those with a positive biopsy of residual disease received salvage treatment with chemoradiation (RT boost of 9 Gy/5 fractions along with cisplatin and 5FU). At 4 years, the addition of mitomycin improved disease-free survival (73% vs. 51%, $p = 0.0003$), colostomy rate (9% vs. 22%, $p = 0.002$), colostomy-free survival (71% vs. 59%; $p = 0.014$) and local-regional recurrence rates (17% vs. 36%, $p < 0.001$). No difference in overall survival was seen. The main toxicities were hematologic, dermatologic and gastrointestinal. Overall acute grade 4 toxicity was higher with mitomycin (23% vs. 7%).

Despite good results with MMC, over 30% of patients still had local relapse and about 40% experience distant relapse [43]. The combination of 5FU and MMC in Nigro's protocol was empirical. Cisplatin is one of the most active agents for squamous cell cancer. It has synergism with both RT and 5FU and would serve as an effective less toxic alternative to MMC. This was tested in few phase II trials which showed encouraging results in terms of response rates and toxicity [51–53]. ACT II trial assessed the efficacy of cisplatin–5FU combination over 5FU–MMC in an RCT in terms of complete response and toxicity [54]. In this 2 × 2 factorial trial, 940 ACC patients of all stages were accrued. Apart from randomization of MMC vs. Cisplatin, patients underwent a second randomization for maintenance chemotherapy. Radiation dose was 50.4 Gy in 28 fractions over 5.5 weeks in both arms. 5FU in both arms was administered at 1000 mg/m^2 continuous infusion for 4 days on day 1 and day 29 of RT. Mitomycin was administered at 12 mg/m^2 bolus on day 1 of RT and cisplatin 60 mg/m^2 on day 1 and day 29. At a median follow-up of 5.1 years, there was no difference in complete response rate (90.5% vs. 89.6%, $p = 0.64$) and overall toxicity (71% vs. 72%) between MMC group and cisplatin group. Grade 3–4 hematologic toxicity was higher in MMC group (26% vs. 16%, $p < 0.001$) primary related to WBC toxicity; however, this did not increase the rates of febrile neutropenia (3% in both arms). Other grade 3–4 toxicities were similar between both arms (skin [48% vs. 47%], GI [16% vs. 18%]). Although the efficacy of cisplatin was similar, the ease of administration of mitomycin (a single dose of MMC given over 10 min) scores over cisplatin (two doses to be given along with hydration over a full day). This trial establishes MMC 5FU along with RT as the standard treatment in localized ACC.

RTOG 98–11 also compared cisplatin 5FU versus 5FU MMC-based chemoradiation [55]. However, the study design incorporated neoadjuvant chemotherapy in the cisplatin arm. Hence, direct comparison of RT with cisplatin or MMC is not possible. The trial showed no difference between the arms in terms of locoregional recurrence, disease-free survival or overall survival. At longer follow-up, both DFS and OS favored 5FU MMC-based chemoradiation [56].

Capecitabine is an oral prodrug of 5FU and is associated with a favorable side effect profile. Its ease of administration (lack of requirement for admission and continuous infusion) and convenience makes it a suitable alternative to 5FU. Capecitabine has safely replaced 5FU in other GI cancers. In rectal cancer, capecitabine has proven efficacy similar to 5FU in neoadjuvant setting [57]. A phase II trial of capecitabine MMC in 31 patients of ACC by Glynne-Jones et al. showed 77% complete clinical response [58]. At a short follow-up of 14 months, three locoregional relapses were seen. Capecitabine was well tolerated with minimal toxicity and good compliance. Another phase II trial by Oliviera et al. showed CR rate of 86% with a locoregional control of 86% at 24 months in 51 ACC patients [59]. Although there is lack of randomized trial proving efficacy of Capecitabine, it is already widely adopted in clinical practice with acceptable toxicity and outcomes [60–63].

Other agents have been explored to enhance the local control rates in ACC. Cetuximab has shown improved survival in Squamous Cell Carcinoma (SCC) of the head and neck and was investigated in ACC [64]. Recently, two phase trials of cetuximab (along with concurrent cisplatin and 5FU with RT) in immunocompetent as well as HIV-positive patients showed reduction of local failure with high incidence of grade 4 toxicities [65, 66]. The role of other targeted agents like Panitumumab is being tested and phase II trials are ongoing (FFCD 0904 trial and VITAL trial) [67].

6.2 Neoadjuvant and Maintenance/Consolidation Chemotherapy

Treatment intensification in ACC to improve survival was tried with neoadjuvant chemotherapy (NACT) and maintenance chemotherapy. Two large RCT trials evaluated the role of (NACT) [55, 68]. RTOG 9811 is multicentric phase III trial which compared cisplatin 5FU NACT (2 cycles) followed by cisplatin–5FU-based chemoradiation with MMC 5FU-based chemoradiation [55]. From 1998–2005, 682 ACC patients were enrolled in the trial with the primary end point being improvement in disease-free survival with NACT f/b CTRT. At a median follow-up of 2.5 years, NACT failed to improve DFS (54% vs. 60%, $p = 0.17$) or overall survival (70% vs. 75%, $p = 0.10$). The locoregional recurrence and DM rates were also similar. The colostomy rates were significantly higher in the NACT-CTRT arm (19% vs. 10%, $p = 0.02$). At a follow-up of 5 years, both DFS (67.8% vs. 57.8%, $p = 0.006$) and OS (78.3% vs. 70.7%, $p = 0.026$) were significantly higher in the CTRT alone arm [56]. Locoregional relapses were less in CTRT arm (20% vs. 27%).

UNICANCER ACCORD 03 trial is a 2 × 2 factorial trial which evaluated NACT and high-dose boost in ACC patients [69]. Two cycles of cisplatin–5FU NACT followed by cisplatin–5FU-based CTRT was compared with cisplatin–5FU-based CTRT. RT dose was 45 Gy in 25 fractions over 5 weeks in both arms. Patients were further randomized to standard boost (15 Gy) versus high-dose boost (20–25 Gy). At a median follow-up of 50 months, there was no difference in colostomy-free survival between NACT-CTRT arm and CTRT arm (76.5% vs. 75%, $p = 0.37$). Five-year OS (74.5% vs. 71%, $p = 0.81$) and local control was also similar.

ACTII trial evaluated the role of maintenance chemotherapy (two courses of Cisplatin and 5FU) after completion of chemoradiation at week 11 and 14 with the premise of reducing distant metastases and improving survival [54]. The primary end point was progression-free survival (PFS). Only 44% of patients could complete both courses of chemotherapy (64% completed at least 1 course); 33% needed dose modifications due toxicity. There was no difference in 3-year PFS between maintenance versus no maintenance group (74% vs. 73%, $p = 0.7$), irrespective of primary randomization to MMC (73% vs. 73%) versus cisplatin (74% vs. 72%). Overall, any grade 3–4 toxicity was seen in 35%; other toxicities were hematologic (7%), GI (13%) and other nonhematologic (29%). There was no benefit of maintenance chemotherapy even in the subset of advanced tumors (T3-4 and node positive). The lack of clinical benefit seen in these trials does not support neoadjuvant or maintenance chemotherapy in the management of localized SCC of anal canal.

6.3 Metastatic Disease

There is no consensus on the management of metastatic ACC, and evidence is limited to retrospective single institutional studies, case series or case reports. Cisplatin 5FU-based chemotherapy is the standard of care in metastatic/recurrent setting [70]. Faivre et al. treated 19 metastatic anal cancer patients at Gustave Roussy Institute with cisplatin–5FU chemotherapy. The regimen consisted of 5FU continuous infusion (1000 mg/m^2 for 5 days) and Cisplatin (100 mg/m^2) on day 2 repeated every 4 weeks. The median number of cycles was four. The response rate was 66% with one CR and 11 partial responses (PR). The median survival was 34.5 months with 1- and 5-year OS rates of 62.2% and 32.2%, respectively. Grade 3–4 toxicity was seen in 13%. Triplet chemotherapy (paclitaxel–carboplatin 5FU) also has been evaluated in first-line setting with 2 patients having a CR [71]. In patients relapsing after first-line chemotherapy, treatment options are limited. The evidence Paclitaxel has shown some activity in patients failing cisplatin–5FU [72]. Recently, Immunotherapy has shown encouraging results in refractory ACC patients. These initial data support further investigation of immunotherapy in ACC patients.

6.4 Chemotherapy Schedules

6.4.1 Assessment

At baseline, CBP with differential counts and platelets, renal function tests and estimated creatinine clearance and liver function test (Bilirubin, AST, Alkaline Phosphatase) are needed to be done. During treatment, CBP with differential counts and platelets and creatinine are needed to be monitored weekly. For patients on warfarin and receiving capecitabine therapy, weekly International Normalised Ratio (INR) is needed to be done until stable warfarin dose established. After treatment, counts should be monitored for 2 weeks after chemoradiation.

Concurrent chemotherapy schedule is shown in Table 2.

Table 2 The chemotherapy for concurrent administration with radiation

Drug	Dose	Administration
Mitomycin C	10 mg/m^2 on day 1 week 1 and on day 29 week 5 (week 5 mitomycin is optional) (maximum dose = 20 mg)	IV bolus.
Capecitabine	825 mg/m^2 BID daily or on days of RT. (Total daily dose = 1650 mg/m^2)	To be taken with or within 30 mins of meal. The second dose to be taken 10–12 h after first dose
5 Fluorouracil	1000 mg/m^2/day for 4 days (days 1–4 on weeks 1 & 5) (total dose = 4000 mg/m^2 over 96 h)	IV in 5% dextrose to a total volume of 192 mL by continuous infusion at 2 mL/h via appropriate infusor device

6.4.2 Toxicity

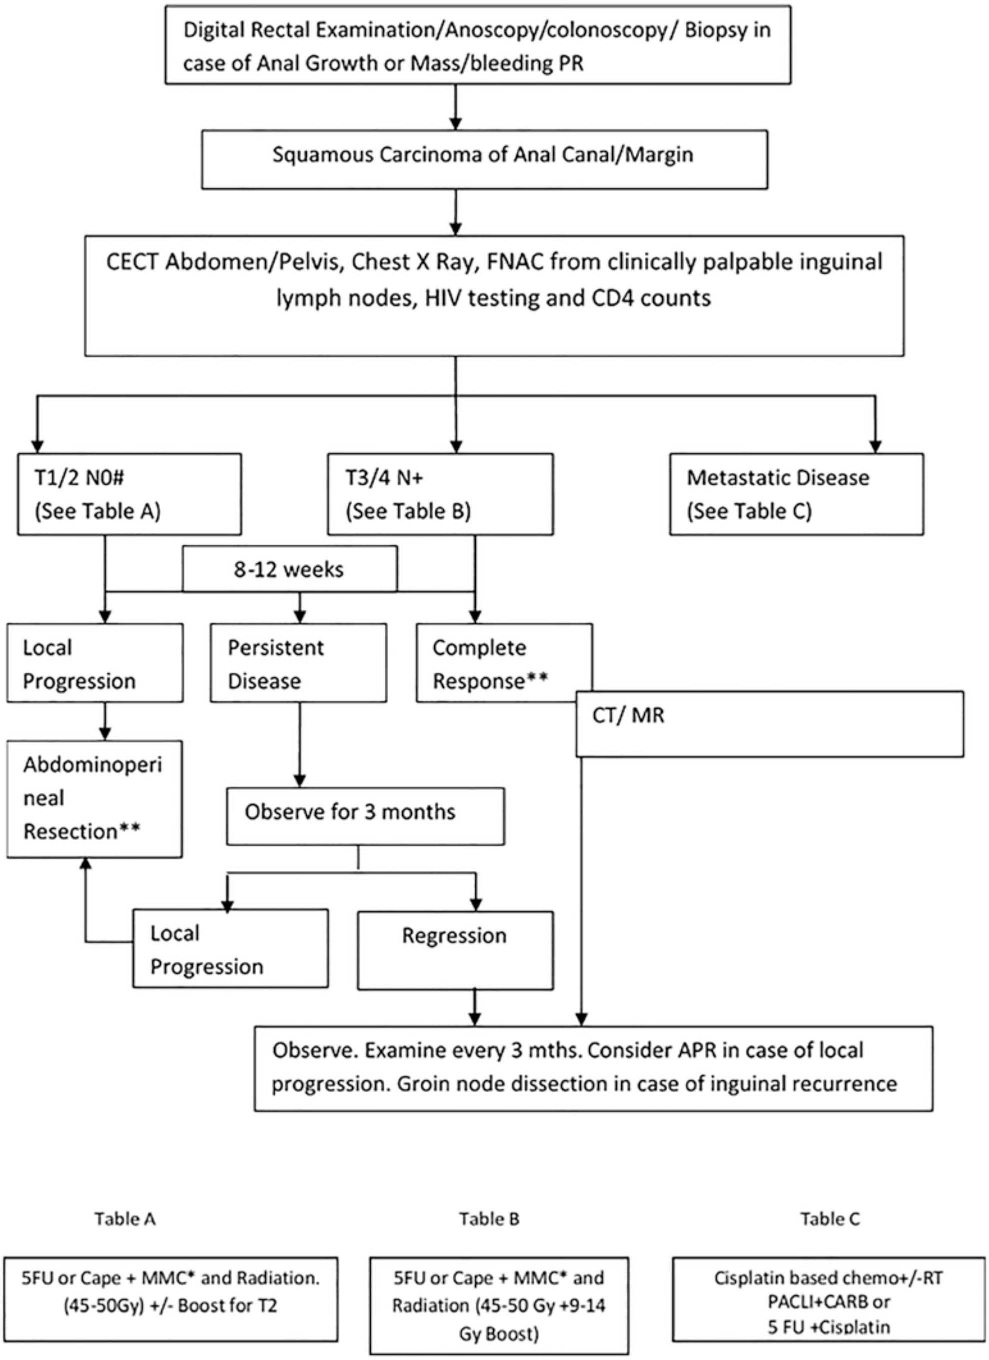
The common toxicities seen are hematologic (anemia, leucopenia, thrombocytopenia), gastrointestinal (diarrhea, stomatitis), hand foot syndrome. Myocardial ischemia or angina occurs rarely with capecitabine or 5 Fluorouracil.

7 Surgical Management

Historically, surgery was the treatment of choice for anal canal cancers. It involved an abdominoperineal resection (APR) of anal canal with permanent end colostomy. The 5-year survival with this approach was around 50–70% [73–75]. With the results of radiation ± chemotherapy, surgery is now reserved for salvage. Few indications for surgery are:

- Anal margin cancer—early stage.
- For the control of primary in locally advanced cases—Poor response or progressive local disease during/following chemoradiotherapy.
- Locally recurrent tumor—local relapse (locoregional) following chemoradiation.
- Failure of locally advanced cases—Persistent local disease or residual lymph nodes after 6 months of completion of chemoradiation.
- Persistent pain, fistula or incontinence following chemoradiation.

A temporary defunctioning colostomy may be needed prior to initiating chemoradiation in case circumferential lesion causing obstruction and involvement of rectovaginal septum



Digital Rectal Examination/Anoscopy/colonoscopy/ Biopsy in case of Anal Growth or Mass/bleeding PR

9 Stage-Wise Prognosis with Current RX (Table 3)

10 Management of Recurrent Disease Including Specific Palliative Measures

Majority of recurrences occur within 2 years of completion of treatment (about 50%) either in primary or in the pelvic/inguinal nodes [76]. Local recurrence or persistence of local disease is an incurable condition and severely affects the quality of life of patients. Patients may present with severe pelvic pain, obstruction, bleeding local infection and incontinence as tumor invades the surrounding tissues. A complete restaging with either PET-CT or CECT thorax, abdomen and pelvis is to be done. If localized disease, salvage APR needs to be considered [77]. If there is extensive local disease and R0 resection is not feasible, a defunctioning colostomy followed by either palliative reirradiation or chemotherapy may be considered.

Gastroenteropancreatic Neuroendocrine Tumors

Rajesh S. Shinde, Vikram A. Chaudhari,
Manish S. Bhandare, and Shailesh V. Shrikhande

Abbreviations

ACTH	Adrenocorticotropic hormone
CRH	Corticotrophin releasing hormone
CT	Computed tomography
EUS	Endoscopic ultrasound
F-NET	Functional NET
GEP-NET	Gastroentero-pancreatic neuroendocrine tumor
IHC	Immunohistochemistry
LAR	Long-acting repeatable
MEN-1	Multiple endocrine neoplasia type 1
MRI	Magnetic resonance imaging
NEC	Neuroendocrine carcinoma
NET	Neuroendocrine tumor
NF-NET	Non-functional NET
NSE	Neuron-specific enolase
PP	Pancreatic polypeptide
PPI	Proton pump inhibitors
PRRT	Peptide receptor radionuclide therapy
SEER	Surveillance, Epidemiology, and End Results
SSA	Somatostatin analogs
TACE	Transarterial chemo-embolization
TARE	Transarterial radio embolization
TS	Tuberous sclerosis
VHL	Von Hippel Lindau syndrome
VIP	Vasoactive intestinal polypeptide

1 Introduction

Gastroentero-pancreatic neuroendocrine tumors (GEP-NETs) is a heterogeneous group of tumors originating from enterochromaffin cells (neuroendocrine) of the gut and are commonly located in the stomach, colorectum, small intestine, and pancreas. In the past, these tumors were described by various terms like APUDomas, Kulchitsky cell tumors, Argentafinomas, carcinoid tumors, and pancreatic islet tumors, accounting for the heterogeneous information and data in the literature [1]. In 2000, World Health Organisation (WHO) developed a universal nomenclature and classification system and termed them as neuroendocrine tumors (NETs). NETs arising from the gastrointestinal tract and pancreas are collectively referred to as GEP-NETs as they share similar treatment principles and guidelines.

2 Epidemiology

The annual incidence and prevalence rate of NETs is rising steadily around the world in recent years, as compared to other malignancies. According to the Surveillance, Epidemiology and End Results (SEER) database, the age-adjusted incidence of NETs has increased from 1.09 cases per 100,000 population in the year 1973 to 6.98 cases per 100,000 population in year 2012. GEP-NETs are more prevalent than most of the epithelial gastro-intestinal cancers except colorectal cancer [2]. This increase in incidence may be probably due to the ready availability of diagnostic modalities, widespread use of imaging, and increased information amongst physicians. GEP-NETs are the most commonly encountered NETs, accounting for 58% of all the NETs. GEP-NETs can occur at all ages but are usually diagnosed after the fifth decade of life and exhibit slight male preponderance. The small intestine is the most commonest GEP-NET site followed by the pancreas, stomach, colon, and rectum. Significant geographical

variation in site predilection is noted and NETs at these sites differ clinico-epidemiologically. GEPNETs usually occur sporadically but 5–25% of cases are associated with some familial or genetic predisposition. Familial syndromes associated with GEP-NETs (particularly pancreatic NETs) are multiple endocrine neoplasia type 1 (MEN-1), von Hippel Lindau syndrome (VHL), von Recklinghausen syndrome (NF-1) and tuberous sclerosis (TS). 53% of patients with NETs present with localized disease, 20% have loco-regional disease, and 27% have distant metastases at the time of diagnosis and there are no identified environmental risk factors [2–7].

3 Pathology, Who Classification and Staging

Multipotent stem cells give rise to all epithelial cells (including neuroendocrine) in the pancreas and gastrointestinal tract. These cells produce a variety of hormones like vasoactive intestinal polypeptide (VIP), gastrin, glucagon, insulin, ghrelin, pancreatic polypeptide (PP), somatostatin, corticotrophin-releasing hormone (CRH) and adrenocorticotropic hormone (ACTH). NETs producing one of these hormones/peptides are referred to as functional NETs (F-NET), while those without any hormone production are termed non-functional NETs (NF-NET).

Neuroendocrine markers like chromogranin A, synaptophysin, neuron-specific enolase (NSE), and CD 56 are expressed by GEPNETs. A thorough description of the macroscopic, microscopic, and immunohistochemical findings is important to support the diagnosis of NETs and to allow a correct classification, staging, and grading. Specific staining for hormones can also be used to confirm the source of clinical symptoms, but the immunohistochemical demonstration of a hormone alone is not proof of the functionality of a NET. The biological behavior of GEP-NETs is dependent on the degree of differentiation and rate of proliferation. Degree of differentiation is the extent to which tumor cells resemble normal cells and the rate of proliferation is defined by the number of mitoses per 10 high-power microscopic fields (mitotic rate), or as the percentage of tumor cells exhibiting immune-positivity Ki-67 antigen (Ki-67 index). Well-differentiated NETs are usually of low or intermediate grade; poorly differentiated NETs are usually high grades (Fig. 1) [8–10]. Immunohistochemistry for Ki-67 (MIB-1) is a must to grade the tumor according to the new World Health Organization (WHO) classification. This classification is applicable to NETs of all sites and has been revised in 2017 (Table 1) [11].

G3 NEC tumors with Ki 67 index <55% are less responsive to platinum-based chemotherapy but still have a good prognosis and survival than chemo-responsive tumors with an index >55% [12]. NETs with lower proliferative index behave more like G2 NETs than aggressive G3 neuroendocrine carcinoma (NEC). New WHO classification proposes G3 NET as a separate group of tumors that behave more like NETs than NECs. These tumors often evolve from a lower grade, usually have Ki 67 index between 20–50%, and mitotic counts less than 20/10 HPF. G3 NETs predominantly show MEN1, DAX, and ATRX mutations, whereas G3 NECs are poorly differentiated with P53 and RB1 mutations and the ki67 index usually is >50%. The most commonly used staging system for GEP-NETs is AJCC -TNM staging system, which has been revised recently. In contrast to the previous edition, NETs are included in the respective organ chapters [13].

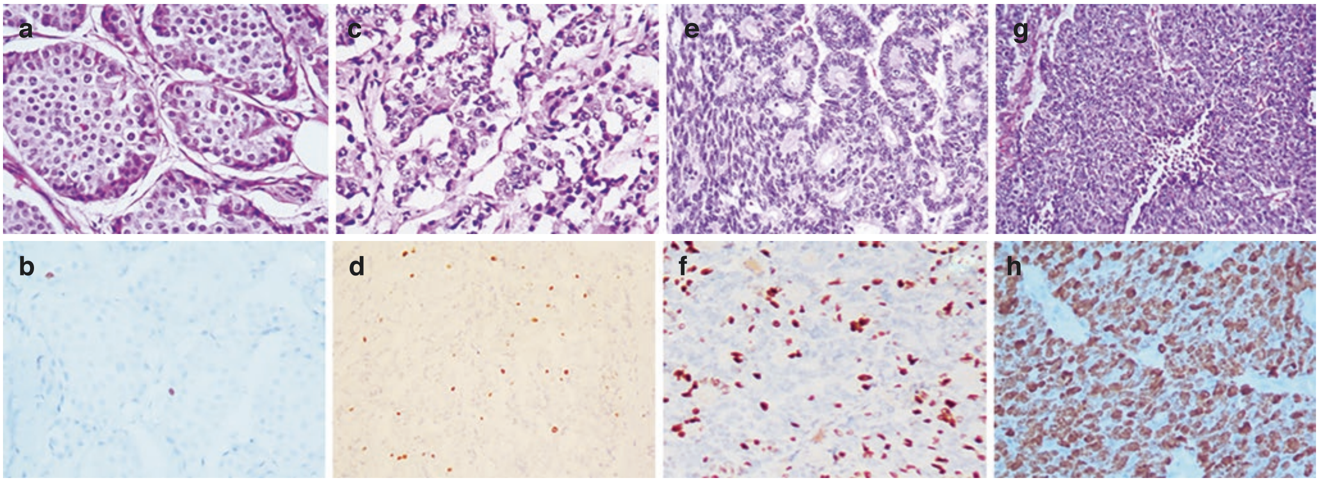

Fig. 1 Microscopic appearance of neuroendocrine tumors. (**a, b**) Grade 1 neuroendocrine tumor with Ki-67 index of 1%. (**c, d**) Grade 2 neuroendocrine tumor with Ki-67 index of 7%. (**e, f**) Grade 3 neuroendocrine tumor with a Ki-67 index of 37%. (**g, h**) Grade 3 neuroendocrine carcinoma with a Ki-67 index of 95%. (**a, c, e, g**) H & E stain. (**b, d, f, g**) Immunostain. Table 1 World Health Organization 2017 classification of the NETs[a]

Grade	Mitotic count (hpf)	Ki-67 index	Morphology
G1 NET	<2/10	<3	Well-differentiated
G2 NET	2–20/10	3–20	Well-differentiated
G3 NET	>20/10	>20	Well-differentiated
G3 NEC	>20/10	>20	Poorly differentiated (small/large cell)
[b]*Mixed endocrine non-endocrine neoplasm (MiNEN):* NETs with a component of a non-endocrine carcinoma (squamous, adenocarcinoma, or acinar cell carcinoma) combined with a neuroendocrine neoplasm. Usually, both components are high grade (G3), but occasionally one of the two or both components may belong to the G1/G2 category. To qualify for a MiNEN, each component should comprise at least 30% of the tumor cell population.			

NET neuroendocrine tumor

[a] This classification was devised primarily for pancreatic NETs. Used with permission from Lloyd RV, Osamura RY, Kloppel G, Rosai J. WHO Classification of Tumours of Endocrine Organs. Lyon, France: IARC; 2017

[b] Features of MiNEN are not detailed in WHO 2017 classification

Poorly differentiated NECs should be staged as per TNM staging for the adenocarcinoma of the respective organ. Further details of AJCC staging can be accessed at https://www.annalsofoncology.org/cms/10.1016/j.annonc.2020.03.304/attachment/05ebe256-f288-45b8-b76d-6fa4403926b3/mmc1.pdf [page 11]).

4 Evaluation and Work-Up

All the cases of suspected GEP-NETs should be evaluated in a stepwise manner to avoid unnecessary investigations and to fast-track the evaluation process.

4.1 Tumor Markers

General/non-specific markers (chromogranin A, Cg A/neuron-specific enolase, NSE) can be elevated in both F-NETs/NF-NETs, whereas specific markers (gastrin, pancreatic polypeptide, insulin) are elevated in F-NETs.

4.1.1 Serum Chromogranin a (cg a)

Serum chromogranin A (Cg A), a glycoprotein marker, secreted by neuroendocrine cells, is raised in both F-NET and NF-NETs. It serves as a predictor of disease burden, response evaluation, and prognostic factors. False positive raised Cg A levels are seen with chronic PPI use, atrophic gastritis, inflammatory bowel disease, renal failure, liver cirrhosis, and malignancies like hepatocellular carcinoma and pancreatic cancer. In patients with poorly differentiated G3 tumors, Cg A is often normal, but serum neuron-specific enolase (NSE) can sometimes be of value as a general marker [14, 15].

4.2 Radiological Imaging

4.2.1 Computed Tomography (CT) and Magnetic Resonance Imaging (MRI) [16, 17]

Cross-sectional imaging in the form of a contrast-enhanced CT scan is the most commonly used and mandatory imaging tool for the localization and characterization of NETs. NETs have rich arterial supply and enhance very well in the early arterial phase (Fig. 2). MRI is occasionally used as an adjunct to CT imaging, they exhibit low signal intensity on T1-weighted sequences and high signal intensity on T2-weighted sequences. NETs are more prominent on fat-suppressed T1-weighted sequences showing low signal intensity as compared to the pancreas. Sensitivities of various imaging modalities are depicted in Table 2.

4.2.2 Endoscopic Ultrasound (EUS) [18]

EUS can detect and localize the lesions as small as 2–3 mm that are missed on CECT and are particularly useful for gastric and pancreatic NETs. It can also be used for obtaining cytology and biopsy to establish tissue diagnosis. However, this is an operator-dependent test requiring skills and expertise.

4.2.3 ^{68}Ga DOTATATE PET CT and ^{18}FDG PET CT Scan [19–24]

Somatostatin, a peptide produced by endocrine cells in the gastrointestinal tract requires attachment to SSTRs, which are coupled to cell membrane G-proteins. Over-expression of SSTRs in NETs forms the basis of SSTR-based radionuclide imaging, where a radiolabeled ligand is used to bind to SSTR. Five SSTR subtypes are known, of which SSTR2 and SSTR5 are abundant, with SSTR2 being particularly useful for clinical practice. PET-CT scan with somatostatin analogs like ^{68}Ga-DOTATATE and ^{18}FDG is the most commonly performed functional imaging in the current era. Potential benefits of these analogs include lower radiation dose, potentially greater diagnostic accuracy, and greater patient convenience. With increasing proliferation (as measured by Mib index or Ki-67), SSTR expression decreases and tumors may not have uptake on SSTR imaging. In such situations, an 18F-FDG PET CT scan can be used. An increased 18-FDG uptake correlates with loss of differentiation, higher grade, and adverse

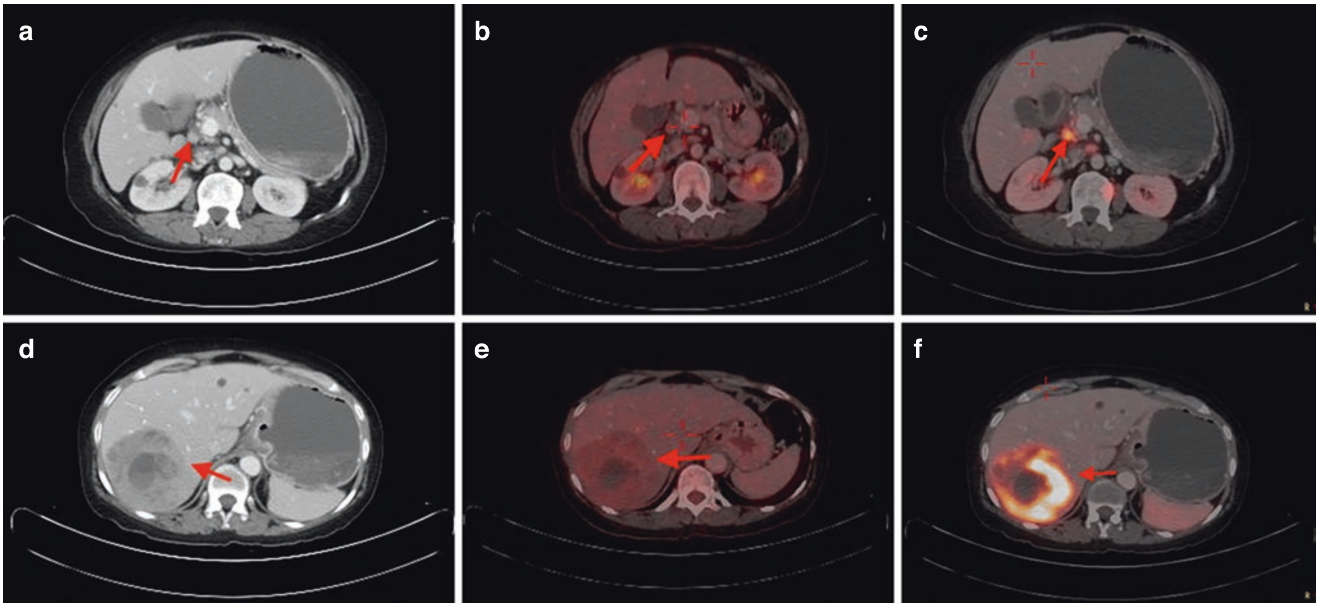

Fig. 2 Radiological appearance of neuroendocrine tumors, small primary lesion at the junction of the first and second parts of the duodenum with a large metastatic lesion in the liver. (**a, d**) Contrast-enhanced CT, heterogeneous enhancement. (**b, e**) FDG PET, low-grade uptake, SUVmax-6.3. (**c, f**) FDG PET, intense tracer uptake, SUVmax-93.44

Table 2 Sensitivity and specificities of different imaging modalities

Imaging	Sensitivity (%)	Specificity (%)
USG	13–27	–
CECT	57–94	83–100
MRI	77–94	78–100
EUS	82–93	87–98
^{68}Ga DOTATOC PET	87–96	88–95

USG ultrasonography, *CECT* contrast-enhanced computed tomography, *MRI* magnetic resonance imaging, *EUS* endoscopic ultrasonography, ^{68}*Ga DOTATOC PET* DOTA positron emission tomography

biologic behavior of the tumor. There is increasing use of dual PET imaging in the current era, especially with higher grade NETs and progressive disease therapy. Besides an improved sensitivity when using hybrid imaging (FDG and DOTA PET), this kind of imaging can also be used for response assessment after peptide receptor radionuclide therapy (PRRT) to evaluate for tumor dedifferentiation or the "flip-flop" phenomenon (high DOTATATE and low FDG uptake in well-differentiated tumors and the opposite imaging phenotype in poorly differentiated tumors). However, the high costs involved limit its availability and use to few centers. SSTR-based imaging for the diagnosis of insulinoma has a lower sensitivity (25–60%), as compared to that for other NETs. The role of various imaging modalities in the evaluation and management of GEP-NETs is elaborated in Table 3.

Table 3 Role of various investigations/imaging modalities in the evaluation and management of GEP-NETs

NET Site	Localization	Staging	Treatment selection
Gastric	CECT, EUS, SRI	CECT+SRI	Endoscopy-resection SRI-SA, PRRT
Duodenum	SRI, EUS	CECT+SRI	SRI: SA, PRRT CECT/MRI: Surgery
Small intestine	SRI, capsule endoscopy, CECT	SRI + CECT/MRI	SRI: SSA, PRRT CECT/MRI: Surgery
Colorectal	Endoscopy, EUS, SRI, CECT	SRI + CECT/MRI	Endoscopy: Resection SRI: SA, PRRT CECT: Surgery

GEPNETs gastroentero-pancreatic neuroendocrine tumors, *CECT* contrast-enhanced computed tomography, *SRI* somatostatin receptor imaging, *EUS* endoscopic ultrasonography, *SA* somatostatin analogs, *PRRT* peptide receptor radionucleotide therapy

4.3 Immunohistochemistry (IHC) [25, 26]

Immunohistochemical staining on biopsy specimens is a must to establish the tissue diagnosis of NETs. While chromogranin A and synaptophysin are the two main and most commonly used IHC markers, CD56, neuron-specific enolase (NSE), and cytokeratin are also important markers, especially in equivocal cases. F-NETs also show expression of peptides such as insulin, gastrin, glucagon, VIP, and somatostatin. Chromogranin A is a specific marker of neuroendocrine differentiation and its positivity is reduced with increasing grade of the tumors. Poorly differentiated NECs may not express chromogranin and may express synaptophysin only. Synaptophysin is a highly sensitive marker but lacks specificity and can be positive in other tumors like acinar cell carcinoma or pseudopapillary tumors. Focal positivity of synaptophysin in the absence of chromogranin A positivity should raise suspicion of pathologies other than NET and the use of additional markers may be necessary.

5 Clinical Presentation

GEP-NETs are a heterogeneous group of tumors, each with specific characteristics and biological behavior. Individual discussion of each entity is beyond the scope of this chapter, however, relevant salient features are elaborated in Table 4 [27–37]. The general outline for the evaluation and management remains the same and is more emphasized here. NF-NETs are more prevalent than F-NETs and the radiological appearance of a hyper-vascular tumor with signs/symptoms pertaining to the specific site remains the most common mode of presentation for these tumors. NF-NETs have poor outcomes as compared to F-NETs, likely due to late presentation.

Table 4 Salient features of gastroentero-pancreatic neuroendocrine tumors

NET	Location	Salient features	Clinical features	Diagnosis	Treatment	5-year survival
Insulinoma	• Equally distributed throughout the pancreas	• MC PNET • ≈ 90% solitary • ≈ 90% benign • ≈ 90% sporadic • ≈ 90% amenable to surgical resection • ≈ 90% are <2 cm. • ≈ 5–10% are associated with MEN 1 syndrome (often multiple)	• Fifth decade of life • females>males • Recurrent attacks of hypoglycemia with blood sugar <50 mg/dL and relief from symptoms of ingestion of glucose. • Neurological symptoms—confusion, visual disturbances, amnesia, altered consciousness • Vasomotor symptoms- sweating, weakness, palpitations, tremor, paresthesias, and hunger.	• 72-h fasting test-gold standard • Whipples triad • Blood glucose levels below 50 mg/dL • insulin levels equal to or greater than 6 mU/mL • Elevated C-peptide levels (> = 200 pmol/L). • Absence of sulfonylurea in the plasma • Arterial stimulation and venous sampling- historical in the current era. • Cross-sectional imaging- CECT • Functional imaging- ^{68}Ga DOTATATE PET/^{18}FDG PET scan	• Surgery • Usually enucleation/ pancreas preserving resection • Percutaneous ablation in unwilling/unfit patients	• 80–95%
Gastrinoma	80% in Gastrinoma triangle (Passaro's)- confluence of cystic and common bile duct superiorly, the junction of second and third parts of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially.	• Second MC PNET • 60% malignant • 50% multifocal • Multifocal tumors in MEN 1 syndrome	• Fifth to sixth decade • Abdominal pain, heartburn, diarrhea • Zollinger Ellison syndrome- pancreatic tumor, symptomatic acid hyper-secretion, and peptic ulceration.	• Serum gastrin levels >1000 pg/mL with gastric pH <2 • Secretin stimulation test • Basal acid output of >15 mEq/h • Cross-sectional/ functional imaging (see above)	• Solitary lesions- surgery with lymphadenectomy. • Multifocal lesions- enucleation of lesions more than 2 cm. • Intractable symptoms/ metastatic disease- PPI/ octreotide/PRRT.	• 50–70%
Glucaganoma	Body and tail	• Rare • 60–70% malignant	• Fifth decade • Equal gender distribution • 4 ds—Diabetes, dermatitis, deep vein thrombosis, depression. • Necrolytic migratory erythema	• Serum glucagon level > 1000 pg/mL • cross-sectional/ functional imaging (see above)	• Resectable- surgery- primary and metastatic sites. • Unresectable- somatostatin analogs for symptom control. • Chemotherapy- dacarbazine, streptozocin.	• 50–60%.

Somatostatinoma	Pancreas, duodenum, and sometimes biliary tract	• 1% of pancreatic NETs • 90% solitary	• Fifth decade • equal gender distribution • Somatostatinoma syndrome-hyperglycaemia, Cholelithiasis, steatorrhea, and diarrhea. • Pain, obstructive jaundice, gastric outlet obstruction, bleeding	• Serum somatostatin level > 160 pg/mL • Cross-sectional/functional imaging (see above)	• Surgery/debulking • Somatostatin analogs	• 20–40%
VIPoma	• Body and tail	• Usually benign • Verner Morrison/WDHA syndrome-watery diarrhea, hypokalemia, achlorhydria	• Fifth decade • Flushing • Weight loss • Secretary diarrhea-painless, odorless, 6–8 L/day	• Serum VIP level > 200 pg/mL • Cross sectional/functional imaging (see above)	• Symptom control-somatostatin analogs, glucocorticoids • Surgery/debulking • Chemotherapy-streptozocin	• 40–50%
Small intestinal NET	• ileum > jejunum >duodenum	• Most common (30–50%) small bowel neoplasm. • 25% are multifocal • 20–30% have carcinoid syndrome • Highest risk of distant metastasis amongst NETs. • Malignant potential is directly correlated with size.	• 6–seventh decade • male>female • Abdominal pain, diarrhea, bleeding • Carcinoid syndrome-episodic flushing, wheezing, palpitations, diarrhea	• Serum chromogranin A and urinary 5-HIAA • Cross-sectional/functional imaging-see above	• Surgery-resection with regional lymphadenectomy • PRRT • Somatostatin analogs	• Localized- 65% • Loco-regional–71% • Metastatic-54%

(continued)

Table 4 (continued)

NET	Location	Salient features	Clinical features	Diagnosis	Treatment	5-year survival
Gastric NET	• Antrum> body>fundus.	• Most common form of GEP-NETs. • 3 types • Type I: MC, associated with chronic atrophic gastritis, hypergastrinemia, and multifocal, polypoidal tumors. • Type II: Associated with hypergastrinemia, underlying Gastrinoma, MEN 1, and small multifocal tumors. • Type III: Sporadic, often large, not associated with hypergastrinemia, and have high malignant/ metastatic potential.	Type I: 6-seventh decade, female>male, s/s of chronic atrophic gastritis, pernicious anemia. Type II: Fifth decade, s/s of Zollinger Ellison syndrome Type III: Sixth decade, males> females, pain	• endoscopy • Type I: High serum gastrin, chronic atrophic gastritis on biopsy, and high gastric pH. • Type II: High serum gastrin and low gastric pH. • Type III: Mass lesion on endoscopy and imaging.	Type I: • <2 cm-Netazepide, endoscopic polypectomy. • >2 cm, >6 lesions, recurrent- surgery. Type II: Treatment of Gastrinoma. • <2 cm-endoscopic resection. • >2 cm, >6 lesions, recurrent- surgery. Type III: Surgical resection with lymphadenectomy.	• Localized- 73% • Loco-regional–65% • Metastatic-25%
Appendiceal NET	• tip of the appendix	• 1 in 300 appendectomies • Usually incidental diagnosis • Malignant potential directly proportional to the size of the tumor	• Fourth decade • females>males • Acute/subacute appendicitis	• Cross-sectional/ functional imaging- see above	• Tumors <2 cm: Appendicectomy • Tumors >2 cm, positive margins or mesoappendiceal involvement: Right hemicolectomy	• Localized- 88% • Loco-regional–78% • Metastatic-25%
Colorectal NET	• rectum> colon • usually mid rectum. • right colon> left colon	• Colonic tumors are more aggressive than rectal tumors. • Malignant potential directly proportional to the size of the tumor	• Males> females • Fifth decade • Rectal bleeding, pain, change in bowel habits	• Endoscopy • Cross-sectional/ functional imaging (see above)	• Endoscopic removal • Transanal endoscopic microsurgery Surgical resection	Colon- • Localized- 85% • Loco-regional–46% Metastatic-14% Rectum- • Localized- 90% • Loco-regional–62% • Metastatic-24%

6 Carcinoid Syndrome and Carcinoid Heart Disease [38–40]

This syndrome is characterized by diarrhea, flushing, and bronchospasm. It is usually seen with small intestinal NETs with liver metastasis. Peptides, particularly serotonin, and prostaglandins secreted by liver metastasis are responsible for the clinical manifestations as these mediators are directly secreted in systemic circulation and spared of metabolism in the liver. Flushing typically involves the face, neck, and upper body and may be precipitated by alcohol, stress, spices, and tyramine-containing foods. Carcinoid heart disease is typically seen in patients with high levels of serum serotonin, causing fibrosis of the right-sided cardiac valves, leading to tricuspid regurgitation and pulmonary valve stenosis. The incidence of carcinoid heart disease is declining, as a consequence of the use of serotonin-inhibiting therapies. Transthoracic echocardiography should be performed annually in patients with carcinoid heart disease; cardiac MRI is helpful in assessing the severity of endocardial fibrosis. Patients with carcinoid syndrome undergoing surgery sometimes develop a circulatory collapse due to the acute release of serotonin and other peptides leading to a carcinoid crisis. Carcinoid crisis is triggered by general anesthesia, epinephrine, handling of tumors, and hence prophylactic octreotide 250–500 μg subcutaneously, 1–2 h before surgery is recommended to avoid the crisis.

7 Principles of Management

Selecting the right modality in the right sequence is crucial for better outcomes in GEP-NETs. It is strongly recommended that such cases are managed in a high-volume center with enough experience and interest in dealing with GEP-NETs. Various modalities available for NETs in the armamentarium of oncologists are surgery, somatostatin analogs (SSA), cytotoxic chemotherapy, targeted therapy, and peptide receptor radionuclide therapy (PRRT). As the literature information is heterogeneous on GEP-NETs, the decision on offering the right treatment in a sequential manner is crucial. The treatment algorithm, followed at Tata Memorial Centre for GEP-NETs is depicted in Figs. 3 and 4. Treatment of functional GEP-NETs differs that from of non-functional GEP-NETs and symptom control takes priority in the former (see Table 4 for details).

Steps in the management of these tumors are as follows:

- Establish the preliminary diagnosis based on clinico-radiological findings.
- Confirm the tissue diagnosis with biopsy and immunohistochemistry.
- Know the functional status- based on symptoms and then specific hormone level estimation (see Table 4).
- Finally, depending on the site, grade, symptoms, and tumor burden appropriate treatment is decided. It is strongly recommended to discuss and plan the treatment in the multidis-

ciplinary meeting. Treatment often involves the integration of multiple treatment modalities like surgery, radionuclide therapy, somatostatin analogs, and chemotherapy.

8 Treatment of Localized/Loco-Regional Tumors [35, 41–45]

Surgery is the mainstay of treatment for localized or loco-regional GEP-NETs. Table 4 depicts the various treatment options for GEP-NETS. The type and extent of surgery depends on the organ involved and disease burden. In general, oncological resection with regional lymphadenectomy is recommended. Small and lower-grade gastroduodenal and rectal NETs can be treated with endoscopic resection followed by regular surveillance. Incomplete endoscopic resection or recurrence following such conservative treatment should be treated with more radical oncological resection. NF-PNET patients with symptomatic, intermediate-to-high grade, or > 2 cm requires formal oncologic surgery. Small, localized PNETs can be managed with enucleation, however, this approach lacks oncologic adequacy in terms of lymphadenectomy and resection margins. Incidentally detected low-grade NF-PNETs, <2 cm in size can be kept under close surveillance.

The choice of surgery in small intestinal NETs primarily depends on tumor location. Jejunal and proximal ileal tumors should be treated with segmental resection and regional lymphadenectomy, whereas tumors in the distal ileum, may require formal right hemicolectomy. Around 25% of small intestinal NETs are multifocal, demanding a thorough inspection and palpation of the entire small bowel intraoperatively. Appendiceal NETs <1 cm are managed with appendicectomy alone, completion with right hemicolectomy is recommended for tumors >2 cm. Rectal NETs can be treated with endoscopic resection, transanal excision, or total mesorectal excision depending on the size of the tumor. Low anterior resection or abdominoperineal resection with lymph node sampling should be performed for larger rectal tumors.

9 Treatment of Advanced/Metastatic/Recurrent Tumors

The current era has witnessed remarkable improvements and development in treatment modalities of metastatic GEP-NETs. Systemic therapy remains the cornerstone in the management of advanced/metastatic/recurrent NETs. Various options for systemic therapy are somatostatin analogs, peptide receptor radionuclide therapy (PRRT), interferon, everolimus, sunitinib, bevacizumab, and cytotoxic regimens. The choice of systemic therapy depends on the primary site, grade, Ki 67 index, SSTR expression, disease burden, functional status, and symptoms. The main objectives of treatment in advanced cases are symptom control and prolongation of survival. Octreotide (long-acting repeatable, LAR), a somatostatin analog is the most commonly used drug for symptom control especially in carcinoid syndrome. Similarly, high-dose proton pump inhibitors (PPI) are used in gastrinoma [46]. Although surgery is not curative in metastatic settings, it still has a definite value in certain clinical situations like small intestinal NETs with obstructive symptoms, mesenteric NETs in close proximity of major vessels, and limited metastatic disease where complete resection of primary and metastatic disease is feasible. Surgery may also be indicated for palliative debulking to decrease tumor burden or to control hormone production. Liver-directed therapies like transarterial embolization, transarterial chemoembolization, and transarterial radio embolization are also options in symptomatic patients with liver-dominant metastatic disease [47–51]. Various studies pertaining to the evaluation of these modalities are summarised in Table 5. It is strongly recommended that all the cases of advanced NETs are discussed in multidisciplinary group meetings for deciding the treatment modality.

9.1 Somatostatin Analogues (SSA)

Octreotide and lanreotide are the commonly used SSAs in GEP-NETs and current evidence suggests that, in addition to symptom control, octreotide also has antiproliferative, and potentially, anticancer effects [52]. PROMID study compared octreotide LAR with placebo in midgut NETs and observed statistically significant improvement in median progression-free survival with octreotide LAR (14.3 vs. 6 months; $p < 0.001$) [53]. CLARINET study, compared lanreotide with placebo and observed significant improvement in progression-free survival (median not reached vs. median of 18.0 months, $p < 0.001$) [54]. These two studies established the role of SSA as the initial line of therapy in advanced NETs for symptomatic relief as well as prolongation of survival. Interestingly, both functional and non-functional NETs derive survival benefits from SSA. A combination of Interferon-alfa and SSA has also been studied, but these studies did not show any benefit of adding interferon to octreotide [55–57]. Currently, there is no evidence to suggest the superiority of octreotide over lanreotide and vice versa, also it is not clear whether treatment with SSAs is better than "watch-and-wait" approach in patients with the very slow-growing disease.

9.2 Chemotherapy

Cytotoxic chemotherapy with cisplatin + etoposide is the primary modality of treatment for patients with grade III neuroendocrine carcinoma. The objective response rate following this combination chemotherapy is around 42–67% with the rapid response but remissions are of short duration. Fit patients progressing on first-line chemotherapy may be offered second-line chemotherapy with FOLFIRI or FOLFIRINOX with varying response rates [12, 58–62]. Grade I-III GEP-NETs not responding or progressing on other modalities can be treated with cytotoxic chemotherapy with streptozocin, 5-FU, temozolomide, or capecitabine. Streptozocin-based combinations regimens have shown response rates in the range of 35–69%. Kunz et al. studied the role of capecitabine + temozolomide versus temozolomide alone in 144, G1/G2 NET patients and found significantly improved progression-free survival with capecitabine + temozolomide (22.7 months vs. 14.4 months, p-0.023) [63–66].

Table 5 Studies evaluating systemic therapies in GEP-NETs

Study	Reference no.	Year	No of participants	Study arms	PFS (months)	*p*-value
Rinke et al. (PROMID)	53	2009	84	Placebo vs. octreotide	6 vs. 14.3	<0.001
Raymond et al.	71	2011	171	Placebo vs. sunitinib	5.5 vs. 11.4	<0.001

PFS progression-free survival, *NR* not reached

9.3 Targeted Therapy

Everolimus, a mTOR pathway inhibitor, is approved for advanced, progressive, well-differentiated, non-functioning GEP-NETs. RADIANT 3 trial randomized 410 patients with low-intermediate grade pNETS to 10 mg everolimus versus placebo and revealed significant improvement in PFS with everolimus (11 months vs. 4.6 months; $p < 0.001$). Other studies (RADIANT 2, RADIANT 4) also observed the same results with everolimus. Because of the significant adverse effects (neutropenia, infections, rash, diarrhea, and hyperglycemia), everolimus is currently reserved/used for patients with significant progression of disease on other modalities [67–69]. Sunitinib, a tyrosine kinase inhibitor, is also approved for use in advanced PNETs. Raymond et al. randomized 171 patients of advanced PNETs into Sunitinib 37.5 mg versus placebo. Median PFS was significantly better with sunitinib (11.4 months vs. 5.5 months; $p < 0.001$) [70]. Usually, both everolimus and sunitinib are commonly used after the progression of SSA and chemotherapy.

9.4 Peptide Receptor Radionuclide Therapy (PRRT)

PRRT is a form of systemic radionuclide-based treatment using the abundance of SSTRs expression (specifically SSTR2) in NETs, to act against NETs. Yttrium-90 (90Y) and Lutetium-177 (177Lu) are the most commonly used radioisotopes for this purpose with reported response rates of 4–38% and 31–55% respectively [71, 72]. Commonly observed side effects with PRRT are nephrotoxicity (90Y > 177Lu), bone marrow insufficiency, myelodysplastic syndrome, and leukemia. Recently, a phase III, randomized control trial, NETTER-1, tested PRRT + octreotide versus high-dose octreotide in patients with advanced, SSTR-positive, midgut NETs who progressed on standard-dose octreotide LAR. Investigators reported a 79% reduction in risk of progression or death with a combination of PRRT+ octreotide ($p < 0.001$) and the trend towards improved overall survival. PRRT with ^{177}Lu-DOTATATE is generally well tolerated, with the commonest adverse events being renal insufficiency (0.4–1.9%) and bone marrow suppression (9.5–11%). Currently, PRRT is approved for use in advanced SSTR +ve, well-differentiated GEP-NETs [73]. Another emerging strategy in higher grade (G2- G3) GEP-NETs, is to combine the use of Capecitabine + Temozolomide chemotherapy with PRRT (chemo-PRRT), with the hypothesis of radio sensitizing action of chemotherapy, this approach is still investigational [74].

9.5 Liver-Directed Therapy

The liver is the most common site of metastatic disease in GEP-NETs. If complete removal of primary as well metastatic disease is feasible, resection is the first choice of treatment in metastatic liver disease. When R0 resection is not possible, liver-directed therapy in the form of transarterial chemo-embolization (TACE), transarterial radio embolization (TARE), and thermal ablation (radio frequency and microwave) are commonly used techniques for the treatment of liver lesions. Liver transplantation has also been successfully used for curative intent treatment in liver-limited metastatic disease. However, there is no level 1 evidence to support the superiority of liver transplant over debulking or medical treatment, also the indications are not well defined. With current available evidence liver transplant can be offered in liver-limited metastatic GEP-NETs of well-differentiated histology and lower grade. Patient age < 55 years, <50% liver involvement, and stable disease after resection of primary are associated with favorable outcomes [75, 76].

10 Follow-Up

Grade 1 GEP-NETs are followed every 6 months and Grade 2/3 GEP-NETs are followed every 3 months. Radiological tests and tumor markers are advised as per the site, stage, and grade of the tumor. For advanced and non-resectable or metastatic GEP-NETs with stable tumors, 6-month intervals are sufficient.

1 Introduction

The incidence of colorectal cancer in India seems to be rising based on hospital registrations. Besides the growing population, other factors like westernization, obesity, and possibly environmental factors may account for this. The rectal cancer management has seen tremendous change over the last few decades. This chapter includes clinical presentation, diagnosis, and current evidence-based management of rectal cancer.

2 Incidence and Epidemiology

As per GLOBOCAN 2018 data, over 1.8 million new cases and 881,000 deaths are estimated to occur in 2018 due to colorectal cancer [1]. Colorectal cancer is now the third most common cancer worldwide in incidence (10.2%). It is the second most common cancer responsible for 9.2% of all cancer deaths. India belongs to countries that are known to be less prevalent for colorectal cancer. But recent years have shown an increase in the incidence rate for colorectal cancer in India. In India, the age-adjusted annual incidence rates (AARs) for colon cancer and rectal cancer in men are 4.4 and 4.1 per 100,000, respectively. The AAR for colon cancer in women is 3.9 per 100,000. As per the national cancer registry program document projected case burden in 2020 for colon and rectum cancer is 51,906 and 46,247, respectively [2]. This rising trend in colorectal cancer is attributed to a change in lifestyle, obesity, etc. Recently a trend has shown a higher incidence of colorectal cancer in young patients and India is no exception to this. A recent retrospective study done at TMC (Tata Memorial Centre) over a year has shown 45.1% of patients are below 45 years of age [3]. While partly contributed by the population pyramid, the reasons for this trend are still unknown.

3 Clinical Presentation

Clinical presentation of rectal cancer mimics benign conditions like hemorrhoids and is often misdiagnosed by local practitioners. A thorough history and proper physical examination including a rectal examination are paramount for early diagnosis of rectal cancer.

Bleeding per rectum is the most common symptom of rectal cancer. Change in bowel habits persisting for more than 6 weeks, unexplained iron deficiency anemia, and significant weight loss are other alarm symptoms that merit urgent investigation.

Spurious diarrhea is the next common symptom. The feeling of incomplete evacuation and tenesmus is common in low rectal cancer. Large or structuring tumors may present with obstruction.

Colicky abdominal pain and bloating sensation are caused by partial bowel obstruction. Lower back pain occurs in locally advanced rectal cancer due to the involvement of nerve trunks.

Other rare manifestations include jaundice due to extensive liver metastases, abdominal distention due to ascites, peritonitis due to perforation, etc.

4 Evaluation and Work-up

4.1 History

Detailed family history should be taken from a patient. Significant family history of familial adenomatous polyposis (FAP) *and* hereditary nonpolyposis colon cancer (HNPCC) necessitates genetic counseling with further investigations.

4.2 Digital Rectal Examination

Digital rectal examination (DRE) confirms the diagnosis, location, and nature of the lesion with high predictive value. High rectal or rectosigmoid lesions are not palpable on per rectal examination. A rigid sigmoidoscopy can examine the rectum for up to 15 cm and is used for accurate location of the lower end of the tumor. Distance from the anal verge gives a good idea about surgical planning and anal canal preservation.

4.3 Biopsy

Histopathological confirmation can be done with proctoscopy or rigid sigmoidoscopy for low rectal lesions or with colonoscopy-guided biopsy for the upper rectal lesion. Any suspicious lesion in another part of the colon should be biopsied. It should be noted that adenocarcinoma of the rectum has three different categories adenocarcinoma, mucinous tumors, signet with different biology, and different responses to chemoradiation [4].

4.4 Blood Investigations

It includes hemogram (CBC), renal function tests (RFT), liver function tests (LFT), and tumor markers (serum CEA and Serum CA 19–9).

Tumor markers levels should be obtained in all patients in the preoperative and postoperative periods. If a previously normalized tumor marker level increases in post-surgery follow-up, it indicates recurrence. Very high tumor markers level indicates advanced metastatic disease [5].

4.5 Colonoscopy

Synchronous colorectal tumors are seen in 2–6% of patients. Synchronous adenomatous polyps are seen in 30% of patients. A complete colonoscopy should be done in all patients to rule out any synchronous lesions in the colon. If colonoscopy is incomplete before surgery, it should be done at 6 months post-surgery. However, the incidence of polyps is relatively low compared to the Western population. A study done over a year in 800 patients at Tata Memorial Hospital has shown 1.4% synchronous malignancies and 9% synchronous polyps [6].

4.6 Radiological Examinations

The following are the investigations done for the diagnosis and staging of rectal cancer:

- Contrast-enhanced CT scan (CECT) (thorax+abdomen+pelvis)
- Magnetic resonance imaging (MRI) (pelvis)
- Endorectal ultrasound (EUS)
- Staging laparoscopy (for near obstructing tumors)

CECT and MRI are essential tests.

CT scan of the thorax is preferred over a chest X-ray as it has more sensitivity and specificity. A recent study at TMC has shown CT chest for staging compared to x-ray chest led to more referrals for pulmonary metastasectomy, the outcome of patients detected with CT was better compared to those detected with x-ray chest alone [7]. CT scan of the chest and abdomen looks for metastatic disease to the liver, lung, retroperitoneal lymph nodes, peritoneal cavity, and

other organs. If contrast is contraindicated, MRI without contrast or PET CT can be done.

Pelvic MRI for local staging is mandatory for patients who are a candidate for resection. Those patients with an extensive metastatic disease, where resection is not an option don't require pelvic MRI. Pelvic MRI assess T and N stage more accurately than CT scan, more important, mesorectal fascia can be seen only on MRI (Fig. 1). Rectal MRI includes T2 weighted images non-contrast, with axial sections perpendicular to the rectum without endorectal coil using either 1.5 or 3-Tesla scans. This helps in planning neoadjuvant therapy, response to neoadjuvant therapy, and plans of surgery (Intersphincteric resection, APER, extra-levator APER, exenteration), it also helps plan whether the anastomosis can be stapled or needs handsewn anastomosis (Figs. 2 and 3) [8]. MRI helps in identifying mesorectal fascia, involvement of mesorectal fascia, and

extra-mesorectal nodes. MRI, however, cannot differentiate between T1, and T2 cancers, and endoanal USG is used to identify T1 patients suitable for local transanal resection or TEM (transanal endoscopic microsurgery) (Fig. 4) [8].

PETCT is routinely not indicated. It should be used in a patient with oligometastatic disease who is treated with curative intent, where it may change management in 8% of cases [9] when CT/MRI has equivocal findings or a patient with a contraindication to IV contrast agent. It is also recommended for rising CEA on surveillance scans compared to routine CT scans.

Staging laparoscopy in near obstructing rectal cancers for creating stoma detects peritoneal metastases and liver metastases not seen on a scan and changes management in more than 20% of cases [10].

4.7 Staging

For staging kindly refer to the AJCC (eighth edition) staging classification for rectal carcinoma [11].

5 Management of Rectal Adenocarcinoma

Outcomes of rectal cancer have improved with increased uptake of total mesorectal excision (TME), MRI for preoperative staging, and neoadjuvant chemoradiotherapy. Management of disease changes as per clinico-radiological staging of disease. Rectal cancer management should be discussed in a multidisciplinary meeting that includes the surgical oncologist, medical oncologist, radiation oncologist, radiologist, and pathologist.

5.1 T1, T2, N0, M0 (MRI Cannot Differentiate Between T1/T2 Cancer, and EUS is Used to Confirm T1 NO Disease)

The following are surgical options available for early-stage rectal cancers:

- Local excision.
- Transabdominal resection.

Early-stage rectal cancers are now diagnosed on screening colonoscopies increasingly. T1 and T2 lesions are accurately diagnosed with MRI pelvis and EUS examinations preoperatively. For these early tumors nowadays, there is greater acceptance for less invasive surgery. We have understood now that tumor biology and risk factors for aggressive disease are the main factors responsible for the prognosis of these lesions. T1 lesions with favorable features have <10% risk of nodal metastases [12, 13].

The following are local options available for early rectal cancer:

- TAE (transanal excision).
- TEM (transanal endoscopic microsurgery).
- TAMIS (transanal minimally invasive surgery).

The advantages of local excision are low morbidity, rapid recovery, and less sphincter dysfunction while disadvantages include more vigilance and risk of recurrence. The local recurrence rate varies from 0–40%.

Criteria for transanal excision:

- T1, SM1 lesions (incidence of lymph node metastasis less than 5%).
- Small lesions (<3 cm).
- Occupying less than the third circumference.
- Low-grade tumors, well to moderately differentiated.
- Within 10 cm from the anal verge.
- Preferably superficial, mobile, polypoidal lesions.
- No e/o enlarged lymph nodes.

5.1.1 TEMS

This is another form of local excision that uses a special type of proctoscope through which dissecting instruments are maneuvered after carbon dioxide insufflation. The advantage of TEM over conventional TAE is that high rectal lesions can be excised with good accuracy. An indication of TEMS is the same as TAE described above. There is a significant learning curve for TEMS.

5.1.2 TAMIS

Atallah et al. described this new technique with the advantages of wider application in the rectum, lesser compromised margins, and low recurrence rates [14]. SILS Port and the GelPOINT Path are the platforms used for this procedure. Pneumorectum is achieved with a more advanced AIRSEAL system. The laparoscopic instrument required is a long 5 mm camera, a grasper, electrocautery, needle drivers, etc. Intraoperative complications are bleeding and entry into the peritoneal cavity. Later complications are rectal stenosis and rectovaginal fistula. There is limited data available for early rectal cancer resection by the TAMIS method. The local recurrence rate varies between 3–9%.

Salvage TME (total mesorectal excision) resection is a standard option in case of local recurrence and adverse TNM features on histopathology.

5.2 T3, N any, M0

It is a consensus that T3, N0, and T1–3, N+ patients should receive neoadjuvant chemoradiotherapy (NACTRT) followed by surgery and then systemic chemotherapy. However, unlike the NCCN mercury group believe that since a T3 tumor (T3A, B) with free CRM and nodes not touching CRM do not impact local recurrence, they can be operated upfront [15]. However, this is not universally accepted. In such cases, we advocate short-course radiotherapy. Surgery of the rectum was revolutionized by a concept of total mesorectal excision (TME). TME involved dissection along the mesorectal fascia to remove the mesorectum completely leading to a significant decrease in local recurrence.

Postoperative chemoradiotherapy has shown a decrease in the risk of recurrence historically (NSABP R-01) [16]. Now there is robust data that show that preoperative chemoradiotherapy significantly downstages a tumor and decreases the local recurrence rate though there is no difference in overall survival (OS).

Principles of surgery:

- Transabdominal resection involves the following types of surgery (Figs. 5 and 6).

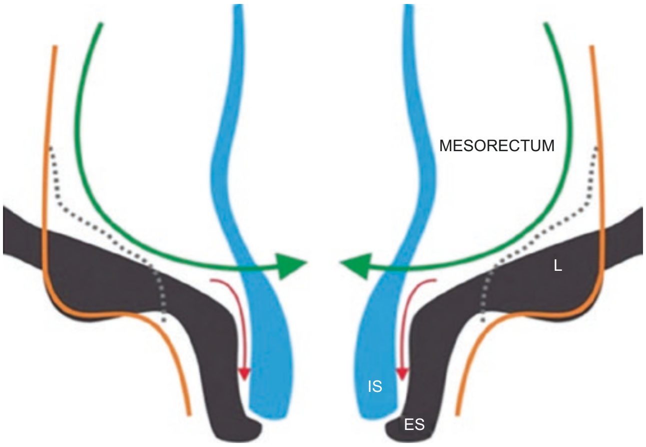

Fig. 5 Incision lines for surgical procedures: Anterior resection (green); Intersphincteric resection (red), APR (dotted), extra levator APR (orange). The sphincter is removed in the latter two surgeries. *ES* external sphincter, *IS* internal sphincter. Images courtesy of Dr. Supreeta Arya

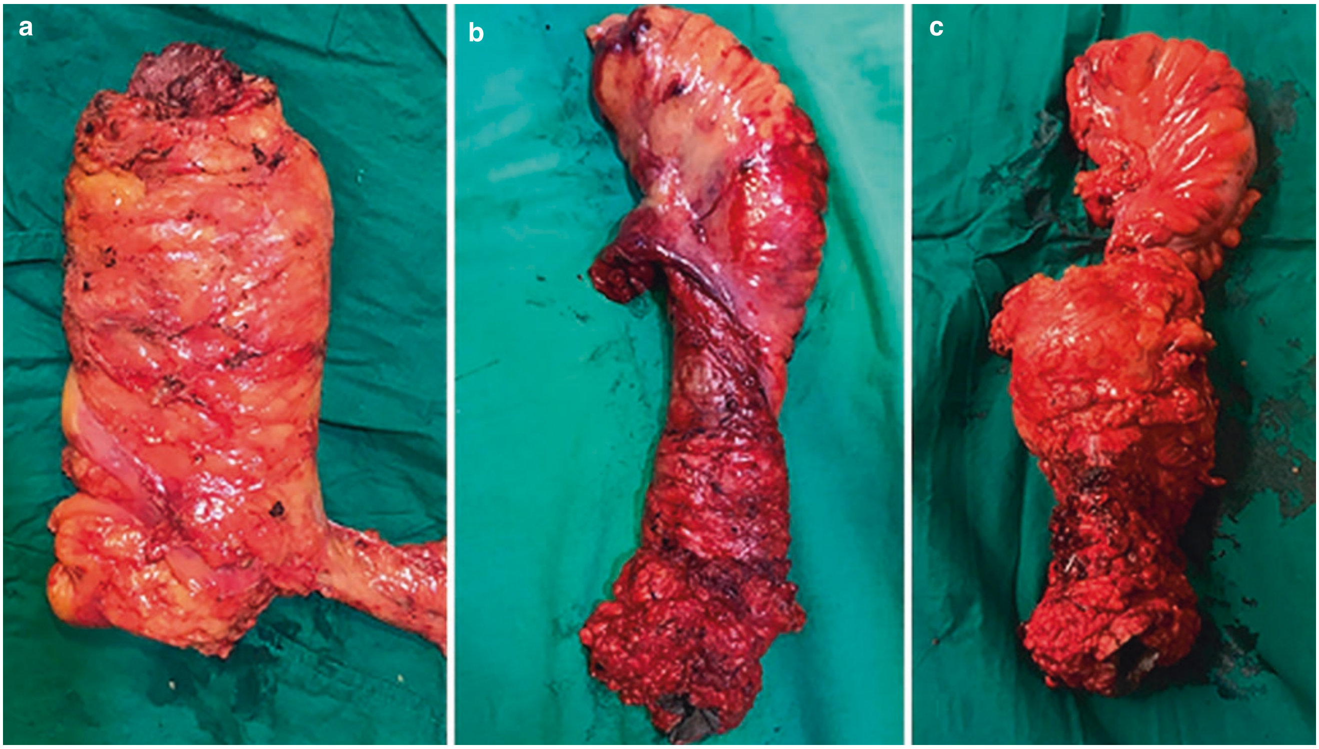

Fig. 6 TME specimen of (**a**) ISR, (**b**) APR, and (**c**) pelvic exenteration

  - Low anterior resection (LAR)
  - Intersphincteric resection (ISR)
  - Abdominoperineal resection (APR)
- Presurgery diversion stoma: Those patients with acute/subacute intestinal obstruction and long-segment disease should undergo diversion stoma. It improves the patient's oral intake and overall nutrition. Pre-operative stenting in near obstructing, obstructive tumors is not recommended as the incidence of procedure-related perforation/ disease's free survival is lower in stented patients [17].
- Surgery should be done 8–12 weeks after a full course of chemoradiation [18].
- After SCRT (short course radiotherapy) surgery can be done immediately after 1 week or after 8–12 weeks.
- A tumor should be excised with adequate margins.
- The proximal margin of 5 cm and distal margin of 5 cm for upper rectal tumors (tumor-specific mesorectal excision), for mid and low rectal cancer, complete TME with 1 cm distal margins is ideal.
- The distal margin should be confirmed tumor-free with a frozen section intra-operatively when possible.
- Total mesorectal excision (TME) is a standard of practice and decreases local recurrence.
- Abdominoperineal resection with a permanent colostomy should be done in patients with levator ani, external sphincter involvement on MRI.
- In APR, the tumor specimen should be cylindrical and one should avoid 'waisting' of the specimen (extra levator APR technique).
- ISR is feasible in those patients with free Intersphincteric space on MRI and good anal sphincter tone.
- Covering diversion ileostomy is preferred in all patients who receive NACTRT, low coloanal anastomosis, and ISR.
- Lymph node dissection: lateral pelvic lymph node dissection is generally done in only those patients in which MRI shows enlarged extra mesorectal nodes after chemoradiotherapy.

5.3 Laparoscopic Versus Open Approach

Open TME resection has been a standard surgical approach in rectal carcinoma. The last two decades have seen a tremendous evolution in minimally invasive techniques. There was concern about minimally invasive approaches regarding complete oncological clearance. Randomized trials have shown that the laparoscopic approach is equivalent to the open approach along with less perioperative morbidity.

The first randomized trial was a CLASICC trial in which 794 patients were randomized for laparoscopic and open approach involving both colon and rectal cancer patients

[19]. Primary short-term endpoints were circumferential and longitudinal margins and in-hospital mortality. CRM (circumferential resection margin) positivity was significantly higher in the laparoscopic group for rectal anterior resection than the open group. It was concluded that laparoscopic resection should not be used routinely. Further long-term studies of CLASICC trial patients have shown no difference in local recurrence, overall survival (OS), and disease-free survival (DFS) [20].

Two other trials COLOR II and COREAN have shown similar results in recurrence, DFS, and oncological outcomes confirming the safety of the laparoscopic approach [21, 22]. COLOR II trial has shown blood loss and postoperative recovery was better in the laparoscopic group. There was no difference between oncological clearance, positive CRM, or distal resection margin between the two groups. Also, mortality within 28 days showed no difference. There was no difference in DFS between the two groups (laparoscopic 74.8% vs. open 70.8 at 3 years). The author concluded that laparoscopic surgery is equivalent in safety with rapid recovery in selected patients treated by skilled surgeons. COREAN trial included 340 patients with mid and low rectal cancer after chemoradiotherapy. There was no difference between the two groups regarding safety, CRM, the number of harvested nodes, and perioperative morbidity. 3-year DFS was 72.5% vs. 79.2% for open and laparoscopic groups, respectively.

Recent two trials (ACOSOG Z6051 and ALaCaRT) which were designed to see non-inferiority of laparoscopic surgery have given controversial results. Both trials have failed to show non-inferiority [23, 24]. In the ALaCaRT trial, successful resection was done in 194(82%) and 208 (89%) for laparoscopic and open groups respectively. CRM was free in 93% of patients in the laparoscopy group and in 97% who underwent open surgery. The distal margin was free in 99% of cases in both groups, and TME was complete in 87% of patients in the laparoscopic surgery group and 92% in the open surgery group. The authors concluded that for patients with T1-T3 rectal cancer, noninferiority of laparoscopic surgery for successful resection is not established. Also, in spite of good quality surgery, it does not provide sufficient evidence for routine use of laparoscopic surgery. Similar evidence was found in the ACOSOG Z6051 trial. 81.7% and 86.9% of patients underwent successful resection in laparoscopic and open groups respectively. This trial did not support the non-inferiority. However, proponents of laparoscopic cite low patient numbers and the use of composite score CRM and DRM (distal resection margin) as a drawback of this study. Near-complete TME and incomplete TME were put in one group, whereas the outcome of complete and near-complete TME is not much different. The 2-year follow-up of this study did not show an inferior outcome in the laparoscopic group (similar to long-term outcomes of MRC Classic (ASOCOG 2018) [25].

The most recent analysis which includes 14 RCT (randomized controlled trials) with 4030 patients has been published in February 2017 [26]. It has concluded, a significantly higher risk of noncomplete resection in patients with laparoscopic resection than open resection. These results questioned the oncologic safety of laparoscopy for the treatment of rectal cancer. However, the long-term results of the MRC CLASICC, COLOR 2 trial, and the 2-year follow-up of ACOSOG did not find any difference in local recurrence disease-free and overall patient survival (Tables 1, 2, and 3).

Table 1 Multicentric randomized trials on laparoscopic rectal cancer resection

Protocol	Years	Number of patients	Distal margin	Completeness of TME	CRM	Long-term recurrence

6 Role of Robotic Surgery in Rectal Cancer

With recent advances in robotics, robotic surgery has shown benefits in terms of vision, precision, and accuracy. Three-dimensional views, seven degrees of freedom, intuitive motion, and tremor filtration offer advantages to surgery as well as to the surgeon. Robotic rectal cancer surgery has great advantages in pelvic rectal surgery, especially in the narrow male pelvis with better-magnified vision and greater dexterity. Precise TME dissection with preservation of the hypogastric nerve with accuracy is possible with robotic surgery. Many retrospective studies and meta-analyses have shown equivalent outcomes as compared to laparoscopic surgery. The recent Robotic versus Laparoscopic Resection for Rectal Cancer (ROLARR) trial has been published [27]. It randomized 471 patients from 29 centers in 10 countries. The primary endpoint of this study was conversion to open laparotomy and similar in both groups (12.2% vs. 8.1%). A study shows no difference in conversion rate (unadjusted risk difference 4.1, −1.4 to 9.6; $P = 0.16$). Besides, no significant differences were seen in TME completion, CRM positivity, rates of intraoperative complications, postoperative complications, or 30-day mortality. There is improvement in conversion rates for robotic surgery versus laparoscopic surgery in men (odds ratio 0.455, 0.209 to 0.987; $P = 0.0429$), obese patients, and low rectal cancer. Robotic surgery provides greater benefits than laparoscopy in the narrower male pelvis. The authors concluded for surgeons with varying workload robotic surgery does not show any advantage over laparoscopy, however, with the learning curve effect, high-volume surgeons may have benefited from robotics.

At Tata Memorial Centre, a propensity cross-match analysis comparing robotic TME and laparoscopic TME has shown no difference in oncological clearance and short-term outcomes between the two groups. Also, this study shows significantly lower anastomotic leak rates and Grade III complications in robotic TME compared to initial laparoscopic rectal surgery (9.5% vs. 1.2%: $p = 0.016$) and (13.1% vs. 4.8%: $p = 0.034$), respectively [28].

7 Transanal Total Mesorectal Excision (TaTME)

Surgery for distal rectal cancer is challenging with a high CRM + ve rate (10%), local recurrence, high morbidity (anastomotic leak rates), and high stoma rates. Abdominal TME is associated with technical constraints viz., difficult visualization of anterolateral planes, neuro-vascular bundle due to difficult angle, posterior dissection requiring lifting and traction, and difficulty in determining DRM which becomes worse in the small narrow pelvis, obese patients, bulky tumor and post-RT fibrosis. Rectal cross stapling often requires 2 or 3 cartridges and hence is associated with high leak rates.

TaTME is combining of transabdominal and transanal approaches to achieve TME. The distal(horizontal) part of the dissection transanally using gel port and laparoscopic instruments enables direct visualization of the distal margin, optimal visualization of the distal TME plane, and better visualization of neurovascular bundles ventrally. Possible benefits include reduced CRM + ve rate, completeness on TME, better sexual function, and lower stoma rate.

Another potential benefit of TaTME is better anastomosis using a double purse-string technique which avoids dog ears (as opposed to LaTME) and crossing of stapler lines, resulting in lower leak rates. Evaluation of the anastomotic line is possible both by direct visualization and reverse leak test using pneumoperitoneum with the option of transanal suture reinforcement.

A systemic review comparing TaTME and laparoscopic TME(LaTME) by Deijen et al. showed a lower CRM positivity rate (3.2% vs. 7.6%) and an increased rate of complete TME (82.8% vs.75.2%) [29]. Pontallier et al. evaluated the functional outcome post-TaTME vs. LaTME and found similar bowel function (LARS score and Wexner score), similar urinary function (IPSS score) but better sexual activity [30]. The reduced need for diversion stoma was reported by Blok et al. with better QOL (quality of life) and lower cost with this approach [31].

A recent survey conducted in Norway has raised serious concerns over the results of TaTME. Out of 157 patients who were operated for TaTME, the local recurrence rate was 11.6% compared to 2.4% in Norwegian colorectal cancer registry patients ($p > 0.001$). anastomotic leak rate was 8.4% vs. 4.5% ($p = 0.047$). Due to these unfavorable rates, TaTME has been suspended in Norway [32].

The TaTME approach is not easy and requires advanced laparoscopic skills, and proper training with a long learning curve. A comparison of laparoscopic vs. transanal TME is being tested in the COLOR III trial.

8 Role of Radiotherapy

The treatment of rectal cancer has changed over time with the introduction of total mesorectal excision (TME), preoperative MRI, the concept of circumferential resection margin (CRM), and neoadjuvant radiotherapy (NART). The majority of trials have shown a decrease in local recurrence (LR) with RT either preoperatively or postoperatively. There has been a paradigm shift in the administration of radiotherapy from adjuvant to neoadjuvant (NA) setting in the treatment of locally advanced rectal cancer (LARC).

8.1 The Rationale Behind Pre-operative RT

The use of pre-operative RT has improved response rates due to the intact blood supply, improved resectability, sterilization of margins, downsizing of a tumor, improved negative CRM(R0) resection rates, increased likelihood of sphincter preservation, pathological complete response(pCR) and better treatment tolerance. Tumor downsizing in turn aids in the easy firing of surgical staplers intra-operatively which is particularly important for low rectal tumors close to the sphincter complex.

8.2 Preoperative RT vs. Surgery Alone

Systemic reviews and meta-analyses have shown decreased LR after RT. A meta-analysis of 11 RCTs by Camma et al., showed significantly lower 5-year LR (OR + 0.49; $p < 0.001$) when preoperative RT was given [33].

8.3 Pre-operative vs. Post-operative Long-Course Chemoradiotherapy

Major trials comparing pre-operative versus post-operative RT favor the use of the pre-operative approach. In the German Rectal Cancer Study Group trial, Sauer et al. randomized 823 patients (T3/4 or N+) into pre-operative long-course chemoRT (NACT-RT) (5040 cGy/28 fractions with 5-FU 1000 mg/m^2/day continuous infusion during week 1 and 5 of RT) and similar post-operative regimen (Tables 4 and 5) [35]. The NACT-RT arm reported significantly lower LR (6% vs. 13%; $p = 0.006$) and higher sphincter preservation rate (39% vs. 19%; $p = 0.004$) with no significant difference in OS. No other trial, however, has shown increased sphincter preservation after CTRT. However, sphincter preservation may increase after CTRT, decrease tumor size to enable stapling, or complete response after CTRT may enable a wait-and-watch protocol.

The Swedish Rectal Cancer Trial randomized 1168 patients to receive either 1 week of RT followed by surgery or surgery alone [36]. After a median follow-up (mFU) of 13 years, patients in the NART arm had lower LR (9% vs. 26%, p 0.001) and prolonged overall survival (OS) (38% vs. 30%, $p = 0.008$). The reduction in LR was observed at all tumor heights, although it was not statistically significant for tumors greater than 10 cm from the anal verge. This trial was, however, done in a pre-TME era.

The Dutch trial, a multi-centric RCT randomized 1861 patients to short-course RT(SCRT), 5Gyx5days followed TME vs. TME alone [34]. Local recurrence (LR) was significantly lower in the SCRT group (5% vs. 11%; $p < 0.001$) with no difference in OS after a mFU of 12 years. Similar results were demonstrated in the Stockholm II trial with lower pelvic recurrence in the SCRT group without any survival advantage [37] (Table 5).

In a meta-analysis by Loos et al., preoperative RT harmed long-term anorectal function but did not significantly affect sexual and urinary function [38].

In another study, MRCCR07 randomized 1350 stage III, rectal cancer patients, into either SCRT followed by TME or surgery followed by selective postoperative chemoRT. SCRT group had decreased LR (4.4% vs. 10.6%; $p = 0.0001$) with similar OS [39].

8.4 Indications for Neoadjuvant RT

Upper rectal cancers above the peritoneal reflection do not benefit from preoperative SCRT or NACT-RT and should be

Table 4 Sphincter preservation rate: German Rectal Cancer Study Group trial

Variable	Preoperative chemoradiotherapy ($N = 415$)	Postoperative chemoradiotherapy ($N = 384$)	*p*-value
Abdominoperineal resection deemed necessary- no (%)	116(28)	78(20)	
Sphincter preserving surgery performed- no./total no (%)	45/116(39)	15/78(19)	0.004

Table 5 RCTs comparing up-front surgery vs. SCRT f/b surgery

Trials	Design	No	FU	LR	OS
A Swedish study [36] (pre-TME-era)	SCRT à surgery vs. up-front surgery	1168	13 years	9% vs. 26%, $p < 0.001$	38% vs. 30%, $p = 0.008$
A Dutch study [34]	SCRT à TME vs. up-front TME	1861	12 years	5% vs. 11%, $p < 0.001$	50% vs. 40%, $p = 0.032$
MRCCR07 [39]	SCRT plus surgery vs. up-front surgery and selective postop CTRT	1350	4 years	4.4% vs. 10.6%, $p = 0.001$	$p = 0.40$

treated like colon cancer. However, at TMH, with the involvement of anterior peritoneal reflection (T4) we offer CTRT, as chances of tumor perforation during surgery decrease; this, however, is being looked at in a study.

Neoadjuvant RT is indicated in:

1. >T3
2. >N0
3. Threatened CRM.
4. Low rectal cancer.

8.5 Addition of Chemotherapy to Pre-operative RT

Combining radio-sensitizing chemotherapy with pre-operative RT has radiobiological rationale with increased response rate and possible early treatment of systemic micrometastasis. A systemic review and meta-analysis which included 4 major RCTs viz., EORTC, EORTC 22921, FFCD9203, and Polish trials supported the addition of chemotherapy to pre-operative RT with significantly increased pCR($p < 0.001$) and lower LR($p < 0.001$) [40]. However, there was no difference in sphincter preservation rate, morbidity, DFS, and OS.

8.6 SCRT vs. NACT-RT

Both SCRT and NACT-RT are feasible options in rectal cancer with comparable results. European nations are a proponent of SCRT whereas the use of NACT-RT is preferred in North America. In the Polish RCT, Bujko et al. compared SCRT (5x5Gy followed by surgery within 1 week) versus NACT-RT (50.4Gy in 28 fractions and infusional 5-FU and leucovorin followed by TME 4–6 weeks later) and found no difference in LR, DFS, and OS [41] However, no pre-operative MRI was done as a part of an evaluation of rectal cancer in this study.

A similar study addressing this issue, the Trans-Tasman Radiation Oncology Group 01.04 trial reported no difference in 3-year LR in both SCRT and NACT-RT arms with similar distant recurrence rates, relapse-free survival, OS, or late toxicity [42]. This trial showed NACT-RT may be more effective in reducing LR for distal tumors. In another phase III RCT, Bujko et al. explored SCRT and consolidation chemotherapy followed by surgery and found the results comparable to NACTRT in terms of R0 resection rates, pCR, and toxicities [43].

LARC can progress on NACT-RT. As per a retrospective study conducted at Tata Memorial Hospital (TMH), poorly differentiated/signet ring (PD/SR) histology had a significantly higher rate of progression both local (32.1% vs. 5.6%, $p = 0.0011$) as well as systemic (35.7% vs. 6.9%, $p = 0.0008$) as compared to well/moderately differentiated adenocarcinoma [44]. Another study from TMH showed progression in 23% of patients with signet-ring (SR) histology on NACT-RT with additional administration of NA chemotherapy [4]. Hence, these patients need to be considered for early systemic therapy, PD/SR histology being a poor biological disease with adverse outcomes.

In TMH, we prefer SCRT in three settings viz., signet ring histology, oligometastatic disease (where early initiation of systemic therapy is warranted), and economic/logistic issues.

8.7 Optimal Interval Between Preoperative RT and Surgery

The interval between NACT-RT and surgery has been suggested to be 6–8 weeks allowing sufficient time for tumor downsizing, facilitating surgery, and improved pCR rates whereas, after SCRT, the surgery is in the following week [18].

It has been shown that delaying surgery more than 6–8 weeks results in more pCR and pCR is related to increased survival. A retrospective study done at Tata Memorial centre has shown that delaying surgery more than 12 weeks does not increase pCR and survival [45]. A Greccar-6 randomized controlled trial randomized 265 patients into 7- and 11-weeks post-CTRT. The primary endpoint was the pCR rate. No difference was found in oncological outcomes in the two groups [46].

In a multi-centric randomized Stockholm III trial, Pettersson et al. demonstrated significant tumor downstaging if surgery was performed at 4–8 weeks post-SCRT [47]. A similar benefit was shown by Bujko et al. [48]. This supports SCRT followed by delayed surgery, an approach that is a viable option in elderly patients who are unfit for chemotherapy.

8.8 Reassessment/Response Assessment After NART

Assessment of tumor response relies on clinical examination (DRE), proctoscopy, and MRI. Appropriate surgical strategy, the type of operation, and the possibility of "watch-and-wait" strategy depend upon the above findings.

8.9 Response to Pre-operative CRT as a Predictor of Outcome

Around 15–27% achieve pCR. Maas et al. have reported improved DFS in those achieving pCR (83.3% vs. 65.6%; $p < 0.0001$). However, it has not translated into increased OS [49].

8.10 Clinical Complete Response and a "Watch-and-Wait" Approach

The "watch-and-wait" (W&W) approach was first introduced by Habr-Gama in patients with clinical complete response (cCR) [50]. Following NACT-RT, cCR can be obtained in 10%–40% of patients.

cCR is defined as follows:

1. The absence of any palpable tumor or irregularity at DRE.
2. No visible lesion at rectoscopy/sigmoidoscopy except a flat scar.
3. Telangiectasia or whitening of the mucosa.
4. Absence of any residual tumor in the primary site and draining lymph nodes on imaging with MRI or ERUS.
5. Negative biopsies from the scar and an initially raised CEA level which returns to normal (< 5 ng/ml).

Dedicated centers have reported encouraging oncological and functional outcome results with this strategy. However, a standardized strict protocol for intensive surveillance is needed.

The OnCoRe project, in a propensity-score, matched analysis, showed no significant difference in 3-year OS with the W&W approach with better 3-year colostomy-free survival than those who underwent surgical resection [51].

The International W&W database (IWWD) has been created to include the W&W registries worldwide (47 institutions across 15 countries) to define guidelines for treatment and surveillance. Long-term outcomes from IWWD in 1009 patients kept on W&W after an mFU 3.3 years revealed the 2-year cumulative incidence of local regrowth of 25.2% (95% CI 22.2–28.5%), distant metastasis rate of 8% and 5-year OS of 85% (95% CI 80.9–87.7%) [52].

W&W is still not the standard of care. At TMH, W&W is offered to patients with cCR if they agree to a close surveillance protocol with the accepted risk of LR. Usually, this approach is avoided in PD/SR histology. Triple assessment–clinical, radiological, and endoscopic evaluation is done every 8–12 weeks in a multi-disciplinary clinic comprising a team of a colorectal surgeon, radiation oncologist, medical gastroenterologist, and radiologist.

8.11 T3, N any, CRM Involved (on MRI)/T4, N Any/Locally Unresectable/Medically Inoperable

Definition of CRM involvement:

1. A tumor within 1 mm of mesorectal fascia.
2. For a lower third of a tumor within 1 mm of the levator muscle.
3. For anal canal tumors invasion into or beyond intersphincteric space.

As discussed above for locally advanced rectal carcinoma NACTRT followed by 8–12 weeks gap and surgery and is standard of care. Those patients who have CRM positive on post-NACTRT MRI should receive 12–16 weeks of chemotherapy (FOLFOX/CAPOX). Post-surgery 6 months adjuvant chemotherapy is recommended.

8.12 Role of NACTRT Followed by NACT

Studies of long-course chemoradiation followed by preoperative chemotherapy for locally advanced rectal cancer have been conducted by several groups. (Table 6) A study conducted by Ostwal et al. at TMH has shown that additional chemotherapy post-NACRT which has unresectable disease improves resection rates, survivals, and downstaging of tumours with acceptable toxicity. FOLFIRINOX (folinic aci d+5FU + irinotecan+oxaliplatin) shows improved survival over CAPOX, specifically in patients who are amenable to conservative surgery post-CRT and CT [53–55].

8.13 Role of Adjuvant Chemotherapy

In all stage II/III rectal cancer following NACTRT and surgery adjuvant chemotherapy is recommended if they did not receive neoadjuvant chemotherapy regardless of the surgical pathology results; however, few studies have evaluated the effect of adjuvant chemotherapy in patients with rectal cancer, and its role is not well-defined.

As per the initial EORTC Radiotherapy Group Trial 22,921, addition of 5-FU as adjuvant chemotherapy to NACTRT provided no benefit, however, had DFS benefit. In the long-term it did not show the OS benefit, however, had DFS benefit [56]. In the phase III ECOG E3201 trial, the effect of adding either oxaliplatin (FOLFOX) or irinotecan

Table 6 NACTRT followed by NACT approach

Study	Inclusion criteria	No.	Treatment	pCR (%)	Outcomes
Zampino, et al. [49]	T3, T4 or N+	51	ChemoRT with capecitabine → × 6 weeks	18	R0 resection—100% 5-year DFS—85.4%
Gao, et al. [50]	T4, bulky (>5 cm), <6 cm from the anal verge, N+, elevated CEA	36	ChemoRT with CAPOX→CAPOX × 3 weeks	36	R0 resection—100% Downstaged—81%

(FOLFIRI) to 5-FU/LV-based adjuvant chemotherapy, found that the FOLFOX could be safely given to the patients [57]. The role of Oxaliplatin in combination with LV/5 FU was underlined by the CAO/ARO/AIO-04 trial and the open-label Phase II ADORE [58, 59].

However, the role of chemotherapy in the adjuvant setting has been conflicting, especially when receiving preoperative treatment in stage II/III tumors. A meta-analysis of four randomized trials (1196 patients) showed that adjuvant fluorouracil-based chemotherapy (5-FU/LV, Capecitabine, or CAPEOX) after preoperative therapy and surgery in stage II/III cancers failed to improve OS, DFS, or the rate of distant recurrences in patients [60]. On the other hand, Peterson et al. in their metanalysis found support for adjuvant 5FU-based chemotherapy [61]. Also, Petrelli et al. in their metanalysis found a positive effect on disease-free survival and overall survival rates with adjuvant chemotherapy. But the evidence is poor due to the significant bias of non-randomised studies [62]. Carvalho et al. in 2017 in their metanalysis found no robust evidence for adjuvant chemotherapy [63].

Given the above conflicting results, adjuvant chemotherapy in rectal cancer remains a standard of care. The preferred regimens include FOLFOX or CAPEOX. The other options though less preferred include 5-FU/leucovorin (5-FU/LV) or Capecitabine, especially in patients whose cancer responded to neoadjuvant treatment with 5-FU or Capecitabine.

The answer to the question of the timing and duration of the therapy is based on the systematic review of a meta-analysis of 10 studies involving more than 15,000 patients done in 2011. The study showed that the OS was decreased by 14% if there is a delay of chemotherapy beyond 4 weeks [64]. So, the answer is the treatment must be started as soon as possible when the patient is medically fit preferably before 4 weeks. The duration of adjuvant therapy is again not well defined however the consensus is 6 months of perioperative therapy.

8.14 Role of Neoadjuvant Chemotherapy Followed by Chemoradiotherapy (Total Neoadjuvant Therapy Approach)

As local recurrence has decreased due to NACTRT and TME, now distant recurrence is a major concern in LARC. Neoadjuvant chemotherapy followed by NACRT is an attractive approach as chemotherapy treats micrometastatic disease and is also believed to increase the pCR rate. Preoperative chemotherapy is better tolerated than postoperative chemotherapy. As most of the data come from phase II trials there is a need to do a randomized phase III trial [65–67]. Recent NCCN guidelines have included NACTRT followed by the NACT protocol for LARC.

8.15 Role of Beyond TME Surgery

In LARC many times multi-visceral resection, pelvic exenteration, and pelvic sidewall resections are required to get R0 margins. With recent advances in neoadjuvant treatment and aggressive surgical strategy, 5-year survival has increased beyond 50%. These surgeries have considerable surgical morbidity. With recent advances in minimally invasive surgeries, these complex surgeries can be performed with less perioperative morbidity and equivalent surgical outcomes [68].

8.16 What Is an Adequate Adjuvant Treatment for Up-Front Resected Stage II, III Tumours?

NCCN guidelines recommend NACTRT for stage II, and III tumors while ESMO guidelines advocate up-front resection for T3N0 tumors without CRM involvement and extramural vascular invasion in upper and mid-rectal tumors. Traditionally, postoperative chemo-radiotherapy was recommended for all stage II-III patients (1990 national institute of health consensus). But routine use of adjuvant CTRT in low-risk cancer is debated. There are not much good quality studies on this. A study was conducted at TMH where upfront resected patients were divided into low-risk and high-risk (T4, N2, LVI/PNI+, CRM +). The study did not show any benefit of adjuvant CTRT over adjuvant CT for low-risk group patients. Thus, it seems that adjuvant CTRT can be avoided in low-risk patients [69].

8.17 T any, N any, M+

Twenty-five percent of CRC patients present with metastatic disease and 35% of patients will develop metastasis on treatment. Treatment of metastatic colorectal cancer has changed from palliative to curative in a selected group of patients. The aim of treatment in mCRC is a cure in selected patients, prolongation of survival, palliation, and increase in quality of life.

Treatment of metastatic rectal cancer generally has the following scenarios

- Limited resectable disease: surgery with perioperative adjuvant chemotherapy.
- Limited unresectable disease: Chemotherapy followed by surgery if possible.
- Widespread and aggressive disease and disease-related symptoms: palliative therapy.

Before starting treatment, it is essential to consider the following factors:

- Patient factors: General condition, emotional status, age, comorbidities, Eastern Cooperative Oncology Group performance (ECOG) status,
- Tumor factors: indolent versus an aggressive tumor, tumor load, and mutational status (RAS and BRAF).
- Treatment goals: Tumour shrinkage to achieve a radical surgery of metastases or palliation, disease control to delay progression, and worsening of the patient's general condition.

9 Treatment of Synchronous Resectable Metastatic Liver/Lung Disease

9.1 Neoadjuvant and Adjuvant Therapy for Resectable Metastatic Disease

Perioperative chemotherapy is recommended in most patients undergoing liver or lung resection to eradicate the residual microscopic disease if any. The total neoadjuvant therapy (TNT) approach is recommended by the panel in 2018 for synchronous lung and liver metastases. Neoadjuvant and/or adjuvant therapy may still be considered in patients with resectable metachronous metastases. Two meta-analyses, one with 3 randomized clinical trials comparing surgery alone to surgery plus systemic therapy and the other with 10 studies with colorectal liver metastases has shown PFS benefit but not an OS benefit [70–72].

EORTC phase III study (EORTC 40983) compared chemotherapy in conjunction with surgery versus surgery alone. It showed the use of perioperative FOLFOX (6 cycles before and 6 cycles after surgery) for patients with initially resectable liver metastases demonstrated absolute improvements in 3-year PFS of 8.1% ($P = 0.041$) and 9.2% ($P = 0.025$); however, there was no OS benefit [73].

The optimal sequencing of chemotherapy remains unclear. It is recommended to use a neoadjuvant treatment approach for patients with synchronous metastases. Metachronous metastases can be treated with neoadjuvant and/or adjuvant systemic therapy.

The advantage of giving preoperative therapy include earlier treatment of micrometastatic disease; determination of responsiveness to chemotherapy, and avoidance of local therapy in those who progress early. The disadvantage includes the risk of disease progression or difficulty in identifying the areas of resection in case of complete response post-chemotherapy [74, 75] and risk of hepatotoxicity (liver steatohepatitis and sinusoidal liver injury) when irinotecan- and oxaliplatin-based chemotherapeutic regimens are administered, respectively [76–80].

To decrease the risk of hepatotoxicity, the neoadjuvant period is usually limited to 2 to 3 months. Patients should be carefully monitored by a multidisciplinary team.

9.2 Dilemma About the Sequencing of Preoperative Treatment Modalities

Various strategies have been developed with various advantages and disadvantages. Therefore, all these patients should be discussed in the multidisciplinary team (MDT) meeting so that a more accurate strategy can be determined with better results. Following are various neoadjuvant strategies:

1. Up-front chemotherapy followed by short-course radiotherapy and delayed surgery.
2. Short-course radiotherapy with subsequent systemic chemotherapy followed by delayed surgery (an approach we follow at TMH).
3. Systemic chemotherapy with intensified chemotherapy regimen in the setting of long-course chemoradiation therapy.
4. Liver-first approach (up-front chemotherapy followed by liver resection followed by CTRT followed by surgery).

10 Treatment of Patients with Limited Unresectable Disease

Neoadjuvant chemotherapy is the preferred approach. The unresectability definition is subjective and depends upon the aggressiveness of the surgeon. Chances of downstaging are 10–15%. Various reports have shown that only 12–33% of patients will have an objective response to result in R0 resection [81–83]. Radiographic response assessment should be done at 6–8 week intervals and surgery should be undertaken as soon as the metastases are resectable. If the primary is resectable, SCRT is preferred before surgery.

There are various regimens used for conversion therapy: FOLFOX, FOLFOXIRI, FOLFIRI+Cetuximab, or panitumumab for RAS, B-RAF wild type.

11 Treatment of Widespread Metastatic Rectal Cancer

Treatment of the widespread metastatic disease is similar to metastatic colon cancer and is discussed in detail in the chapter on colon cancer.

12 Management of Recurrent Rectal Cancer

Local recurrence after rectal cancer resection has decreased over the last two decades, however, in patients with locally advanced disease, recurrence after local resection occurs in 5–15% of patients. Almost half of these will present with unresectable systemic metastasis and in these cases, palliative treatment in the form of chemotherapy/radiotherapy is offered.

Selected few patients eligible for resection can undergo APER, pelvic exenteration / sacrectomy with 5-year survival over 35% if R0 resection is achieved [84, 85].

Follow-Up

1. After curative-intent surgery and adjuvant chemotherapy:

1–2 years/ 3 monthly	Sr CEA, Sr CA 19–9, clinical examination
3 year/6 monthly	Sr CEA, Sr CA 19–9, clinical examination
4/5 year/yearly	Sr CEA, Sr CA 19–9, clinical examination

CECT (Thorax+Abdomen+Pelvis): should be done yearly.

Colonoscopy: Every 1 year after surgery and every 5 years thereafter. If presurgery colonoscopy is incomplete due to obstruction then should be done at 6-month post-surgery.

PETCT: Not recommended.

Routine CEA and CT scans are not recommended after 5 years.

2. After lung/liver resection

1–2 years/ 3 monthly	Sr CEA, Sr CA 19–9, Clinical examination
3 year/6 monthly	Sr CEA, Sr CA 19–9, clinical examination
4/5 year/yearly	Sr CEA, Sr CA 19–9, clinical examination

CECT (Thorax+abdomen+pelvis): Every 6 months for 2 years then every 12 months thereafter till 5 years.

PETCT: Not recommended.

Colonoscopy: Every 1 year after surgery and every 5 years thereafter. If presurgery colonoscopy is incomplete due to obstruction then should be done at 6-months post-surgery.

Amit Narendra Chopde, and Manish S. Bhandare

Abbreviations

BRPC	Borderline resectable pancreatic cancer
DWI	Diffusion-weighted imaging
ERCP	Endoscopic retrograde cholangiopancreatography
EUS	Endoscopic ultrasonography
IPMN	Intraductal papillary mucinous neoplasm of the pancreas
MCN	Mucinous cystic neoplasm
MDCT	Multi-detector computed tomography
MRCP	Magnetic resonance cholangiopancreatography
NCCN	National Comprehensive Cancer Network
PV	Portal vein
SBRT	Stereotactic body radiation therapy
SMV	Superior mesenteric vein

1 Introduction

Pancreatic cancer has a dismal prognosis with incidence and the mortality curves running parallelly [1]. Despite treatment advances, 5-year survival across all stages remains as low as 6–7%. This is attributable to many factors but perhaps the most important reason is the late diagnosis in advanced stage. Most patients remain asymptomatic until the disease progresses to an advanced stage and only 20% of patients are eligible for resection at presentation [2]. Despite curative resection, the reported 5-year survival rate for resected cases remains low up to 25% [1]. This aggressive tumor biology leads to early recurrence and metastasis. In this review, we discuss epidemiology, risk factors, diagnosis, and management of pancreatic cancer.

2 Epidemiology: Indian and Global Scenario

Pancreatic cancer is the 13th most common cancer in the world and eighth most common cause of cancer-related deaths amounting to about 200,000 deaths per year worldwide [3]. Incidence in Europe and USA is also rising with pancreatic cancer being projected to be the second leading cause of cancer deaths in USA by 2030 [3]. The incidence of pancreas cancer is lower in Indian, African, and southeast Asian population; however, these estimates are marred by under-reporting. In the Indian context, the reported incidence is 0.5–2.4 per 100,000 men and 0.2–1.8 per 100,000 women [4, 5].

Pancreatic cancer is predominantly a disease of elderly commonly seen among patients between 60 and 80 years of age [6]. Indian population seem to be affected by the disease earlier with a younger median age of presentation (52–55 years) [7, 8]. It is also seen more commonly in men as compared to women with a male to female ratio of 1.5:1 [5].

3 Risk Factors

Cigarette smoking is the most common and well-documented risk factor for developing pancreas cancer. Even after cessation for at least 10 years, there is 75% increased risk as compared with general population [9]. Chronic pancreatitis is another factor associated with raised lifetime risk of pancreatic cancer [10]. Diabetes is not merely a marker of pancreatic dysfunction as a result of neoplasia but a risk factor for cancer as diabetic patients have an additional 30% risk of pancreatic cancer that persists for more than 20 years after initial diagnosis of diabetes [11]. Advancing age is strongly associated

with pancreatic cancer with 20 times higher risk for individuals older than 50 years as compared to younger persons and the median age at presentation being 71 years. Though alcohol is a risk factor for developing pancreatitis, studies have failed to show its association with pancreatic cancer [12, 13]. Similarly, although 10% cases of pancreatic cancer are familial, the genetic basis for most remains unknown. Several genetic syndromes have been associated with pancreatic cancer, but these account for a few cases of familial pancreatic cancer (Table 1) [14–16]. Obesity, specifically high body-mass index (BMI) and centralized fat distribution is also known to increase the risk for pancreas cancer [17].

4 Clinical Presentation

In early stage of the disease, usually patients are asymptomatic. With advancing stage, patients start manifesting symptoms, and the most common presenting symptoms are pain, jaundice, and weight loss. A large case-control study that compared the incidence of early pancreatic cancer symptoms reported 12 alarm symptoms for pancreatic cancer: weight loss, abdominal pain, nausea and vomiting, bloating, dyspepsia, new-onset diabetes, changes in bowel habit, pruritus, lethargy, back pain, shoulder pain, and jaundice [18]. Back pain, lethargy, and new-onset diabetes are unique features of pancreatic cancer. Unexplained superficial thrombophlebitis that may sometimes migrate (classic Trousseau syndrome) is also reported with pancreatic cancer, and it reflects the hyper-coagulable state associated with pancreatic cancer [19]. Some patients develop skin manifestations which are paraneoplastic phenomena.

Tumor location within the organ impacts the initial presentation. Approximately 60–70% of exocrine pancreatic cancers are located in the head of the pancreas, while 20–25% are in the body/tail [20]. Head tumors often present with jaundice, steatorrhea, and weight loss while body and tail cancers more commonly have backache and abdominal pain [21]. Metastatic disease can also manifest as presenting symptoms. Metastasis commonly occurs in liver, peritoneum, lungs, and, less frequently, bones with presentation varying as per organ involved. The presence of an abdominal mass, ascites, left supraclavicular lymphadenopathy (Virchow's node), palpable periumbilical mass (Sister Mary Joseph's node), or a palpable rectal shelf suggests advanced incurable cancer.

5 Evaluation and Work-Up

The diagnostic evaluation for these patients includes serologic evaluation and abdominal imaging. Further testing is based upon the findings of the initial tests and clinical presentation and risk factors. Patients with jaundice or epigastric pain should have an assay of serum aminotransferases, alkaline phosphatase, and bilirubin to determine if cholestasis is present. In addition, patients with epigastric pain and a history suggestive of acute pancreatitis should also be evaluated with a serum amylase and lipase.

5.1 Tumor Markers

Out of many serum markers for pancreatic cancer, the most useful is carbohydrate antigen 19-9 (CA 19-9) with sensitivity and specificity rates ranging from 70% to 92%, and 68% to 92%, respectively. CA 19-9 levels at initial presentation and in the postoperative setting serve as prognostic markers and as an indicator of disease activity in patients with initially elevated levels [22, 23]. In patients with potentially resectable pancreatic cancer, the preoperative CA 19-9 level also helps in prediction of radiographically occult metastatic disease leading to better selection of cases for staging laparoscopy in order to avoid futile laparotomies. In addition, serial monitoring of CA 19-9 levels (once every one to three months) is useful in postoperative surveillance and to determine serologic response in those receiving chemotherapy for advanced disease. The rise in CA 19-9 levels is usually observed before the recurrent disease is appreciated on imaging [22, 23].

5.2 Imaging Modalities

5.2.1 Transabdominal Ultrasonography

Owing to operator dependence and patient's factors like obesity and bowel gas hampering visualization of pancreas, the sensitivity and specificity of transabdominal ultrasound for pancreatic cancer remain low varying from 75% to 89% and from 90% to 99%, respectively [24].

5.2.2 CT Scan

Contrast enhanced multi-detector computed tomography (MDCT) is useful for the diagnosis of suspicious pancreatic lesions, assessment of resectability and vascular invasion as well as diagnosis of metastatic lesions and has become the imaging modality of choice [25].

Characteristic CT findings diagnostic for pancreas cancer [26]:

- Hypo-attenuation (sensitivity 75% and specificity 84%)
- Ductal dilatation (50% and 78%)

- Ductal interruption (45% and 82%)
- Distal pancreatic atrophy (45% and 96%)
- Pancreatic contour anomalies (15% and 92%)
- Common bile duct dilation (5% and 92%)

Comprehensive imaging of a suspected pancreatic cancer patient includes several dynamic phases of contrast injection termed as "pancreas protocol" CT scan.

It consists of the following phases:

- The arterial phase of enhancement: Includes first 30 seconds after the start of the contrast injection, yielding excellent opacification of the celiac axis, superior mesenteric artery (SMA), and peripancreatic arteries.
- •Pancreatic phase: A period of 40–50 seconds after contrast injection having best attenuation difference between the tumor and normal pancreas, which increases the lesion conspicuity. This is best achieved after peak enhancement of the aorta in the arterial phase but before peak enhancement of the liver, which occurs in the portal venous phase.
- The venous phase: Taken at 60–70 seconds after the start of the contrast injection, the venous phase yields superior enhancement of the superior mesenteric, splenic, and portal veins. Additionally, it also gives peak hepatic enhancement optimizing the detection of hepatic metastases.

Overall accuracy of MDCT for diagnosis is about 90%. The accuracy of MDCT to define resectability is 85–95% [27, 28].

5.2.3 MRI

The sensitivity (83–85%) and specificity (63%) of gadolinium-enhanced MRI are similar to that of MDCT [29]. Diffusion-weighted imaging (DWI) is an MRI technique utilizing the Brownian motion of water molecules in tissue [30]. MRI-DWI could be preferred to CT as it facilitates precise depiction of pancreatic lesions without radiation exposure. Magnetic resonance cholangiopancreatography (MRCP) allows the noninvasive picturisation of the pancreatic duct and biliary tract. It is particularly useful for diagnosis of small pancreatic masses and has almost replaced invasive endoscopic retrograde cholangiopancreatography (ERCP) for this purpose. However, it does not permit tissue sampling [31]. It is also useful in intraductal papillary mucinous neoplasm of the pancreas (IPMN) and in chronic pancreatitis, both of which may be associated with pancreatic cancer.

5.2.4 PET

FDG-PET plus CT is not clearly shown to have an advantage for diagnosing pancreatic cancer compared with contrast enhanced MDCT [32]. False negative results in hyperglycemia and possible false positive results in inflammatory masses caused by pancreatitis limit the use of this modality.

5.3 Endoscopic Techniques

5.3.1 ERCP

Brushing cytology and aspiration cytology using an endoscopic naso-pancreatic catheter placed during ERCP are reported to improve the diagnostic accuracy in pancreatic cancers [33, 34]. Moreover, probe-based confocal laser endomicroscopy is highly sensitive to diagnose cancer in pancreaticobiliary strictures [35]. However, with availability of MDCT and dynamic contrast MRI, ERCP for diagnosis has almost become obsolete. ERCP definitely has a therapeutic role in pancreatic head cancers with biliary obstruction and a very high jaundice (>15 mg/dL) or symptomatic jaundice (fever, features of cholangitis). After stenting, it is prudent to delay the surgery (pancreaticoduodenectomy) for 4–6 weeks in order to minimize infections complications and improve postoperative outcomes [36].

5.3.2 Endoscopic Ultrasonography

Endoscopic ultrasonography (EUS) has high sensitivity and specificity to detect pancreatic cancer. EUS-guided fine-needle aspiration has accuracy of more than 85–90% for pancreatic cancer.

In summary, MDCT with angiography or MRI/MRCP should be the first imaging modality in a patient suspected with pancreatic cancer. EUS is recommended to assess highly suspicious lesions which are not clearly demonstrated on CT/MRI and in borderline resectable tumors for assessment of vascular involvement. It also helps in obtaining a tissue diagnosis. Role of PET-CT is limited to ruling out distant metastasis in locally advanced lesions [37].

5.4 Pathology

5.4.1 Histopathology

Pancreatic ductal adenocarcinoma is the commonest pancreatic neoplasm which is invasive mucin-producing gland-forming tumor. A strong stromal desmoplastic reaction is commonly seen in surrounding region. Most pancreatic adenocarcinomas arise from noninvasive precursor lesions known as pancreatic intraepithelial neoplasms [38]. Few of them have cystic precursors—namely, IPMNs and mucinous cystic neoplasms (MCNs).

Pancreatic adenocarcinoma is divided into three grades (well, moderately, and poorly differentiated) depending upon the degree of differentiation. Several key features must be documented in the histopathology report while analyzing any pancreatic resection specimen for pancreatic cancer. Tumor size and invasion into surrounding structures have to be carefully assessed for accurate determination of the T stage. It has been recommended that at least 15 nodes are required for accurate N staging [39]. All margins, including the proximal (gastric or duodenal), distal (duodenal), uncinate, bile duct, and pancreatic resection margins should be checked for presence of invasive carcinoma component. A standardized protocol pancreaticoduodenectomy specimen evaluation involving margin staining, axial slicing, and tissue sampling has been proven to influence reporting of resection margins [40, 41].

5.4.2 Molecular Pathology

Four major driver genes have been described for pancreatic ductal adenocarcinoma (one oncogene and three tumor suppressor genes) [42–44].

- KRAS: Encodes a small GTPase mediating downstream signaling from growth factor receptors and is the commonest oncogene involved. Somatic mutations in KRAS gene are seen in more than 90% of tumors.
- CDKN2A: Most frequently altered tumor suppressor gene with loss of function in more than 90% of ductal adenocarcinomas, it encodes a protein essential for cell-cycle regulation.
- TP53: A tumor suppressor gene plays a key role in the cellular stress response and is mutated in a wide range of tumor types.
- SMAD4: This tumor suppressor gene mediates signal pathway downstream of the transforming growth factor β (TGFβ) receptor and its inactivation is seen in about 50% of pancreatic ductal adenocarcinomas.

Recent studies have identified alterations in hundreds of other genes in carcinogenesis of pancreatic adenocarcinoma. However, it is difficult to differentiate driver genes that causally contribute to development of cancer from the passenger genes which aggregate random mutations during cell division.

5.5 Referrals Including Genetic Counseling

Familial predisposition is seen in approximately 10% of pancreatic cancers. The exact genetic basis for this predilection is unknown in most cases, and 80% of patients with a family history of pancreatic cancer do not have any known genetic cause [11]. Patients with suspected hereditary cancer syndrome should be considered for genetic counseling [45]. A thorough family history specifically of pancreatitis, melanoma, and cancers of the pancreas, colon/rectum, breast, and ovaries should be noted. Family history of cancer, young age, as well as Ashkenazi Jewish ancestry should lead to a referral for genetic counseling. At-risk family members should also be offered genetic counseling. Patients with a significant family history should be advised on risk-modifying strategies like smoking cessation and weight loss.

6 Principles of Management

Treatment of pancreatic cancer varies according to the stage with a multimodality and multidisciplinary approach that includes surgery, chemotherapy, and radiation therapy as well as symptom relief and palliative care. Baseline performance status, comorbidities, and goals of care must be taken into consideration before planning the treatment.

During the evaluation process, nonmetastatic patients are categorized into resectable, borderline resectable, or unresectable tumors [46] (see Fig. 1a–c).

Primary surgical resection should only be offered to patients with resectable tumors with good performance status and a favorable comorbidity profile appropriate for a major abdominal operation. Following resection, all patients are offered adjuvant chemotherapy. Patients who undergo R1 resection are considered for additional adjuvant radiotherapy.

Tumors with venous involvement of the superior mesenteric vein or portal vein, gastroduodenal artery encasement up to the hepatic artery, and abutment of the superior mesenteric artery of ≤180° are considered as “borderline resectable.” The risk for incomplete (R1) resection with upfront surgery in these cases is high and hence, downstaging with neoadjuvant chemotherapy or chemoradiotherapy and reassessment for curative resection is the preferred approach.

Tumors with >180° encasement of superior mesenteric artery, celiac axis, non-reconstructable superior mesenteric vein involvement or superior mesenteric-portal vein confluence occlusion, or direct infiltration of the inferior vena cava and aorta are considered unresectable cancers. These patients are managed initially with chemotherapy with or without radiotherapy. A small fraction of these tumors may respond well enough to chemotherapy and/or radiotherapy to warrant consideration for surgical resection (conversion chemotherapy).

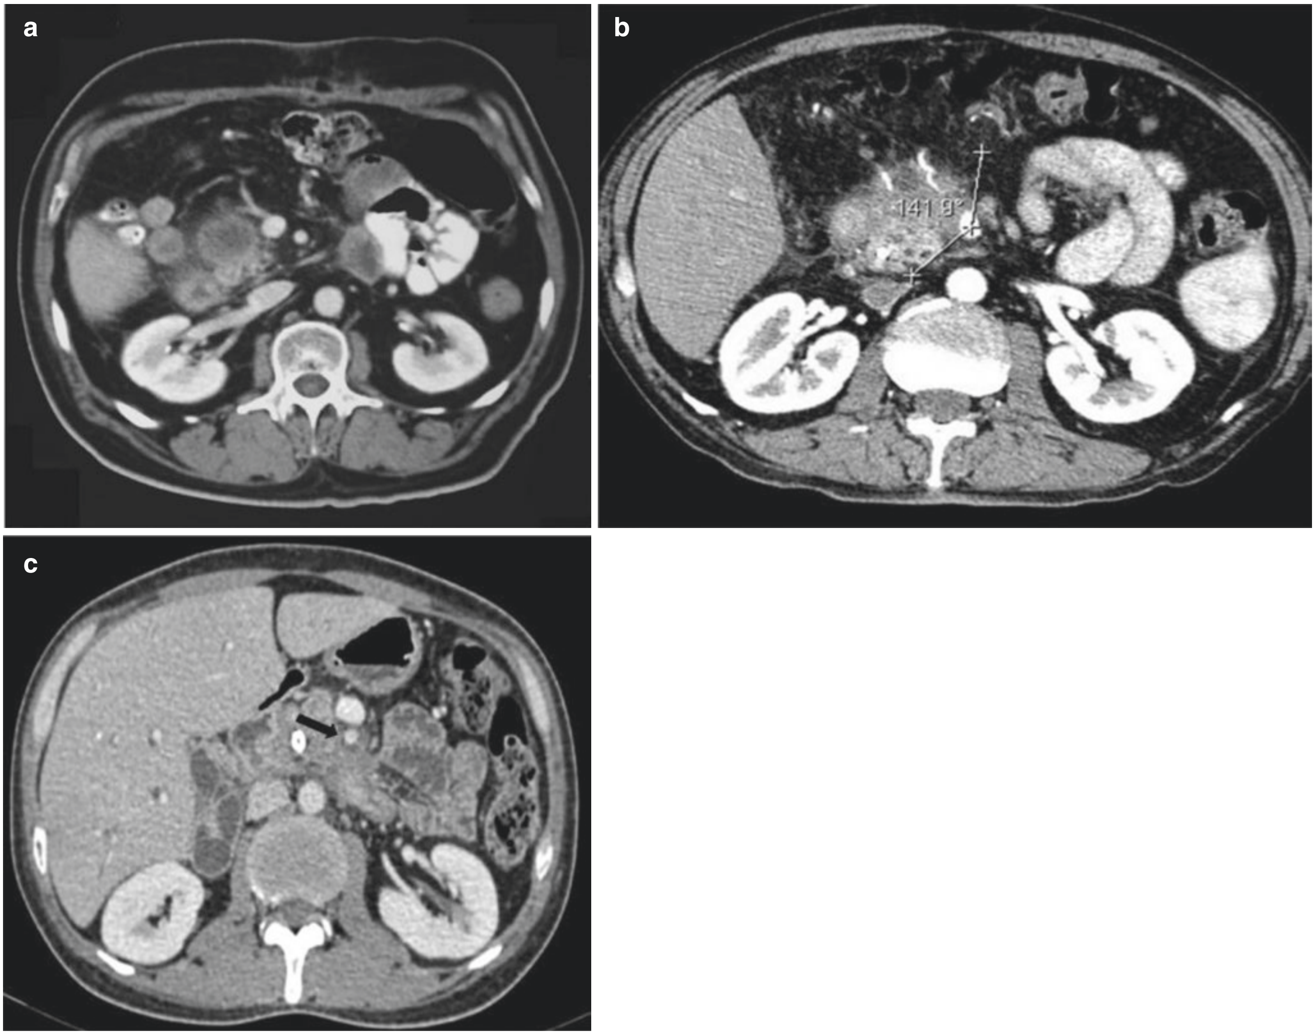

Fig. 1 (**a**) Resectable pancreatic cancer without involvement of surrounding vasculature. (**b**) Borderline resectable pancreatic cancer complete involvement with non-visualization of SMV/PV and SMA involvement of <180°. (**c**) Locally advanced pancreatic cancer with encasement of superior mesenteric artery >180°

7 Surgical Management

7.1 Indication for Surgery

Regarded as the only available treatment option with potential for achieving cure, surgical resection results in significantly longer survival compared with any other treatment options. Superior mesenteric vein (SMV) and portal vein (PV) involvement was considered to be unresectable in the past. However, curative surgery including SMV/PV resection and vascular reconstruction has become standard of care in specialized high-volume centers.

Nonmetastatic pancreatic cancer can be divided into three categories:

1. Resectable
2. Borderline resectable
3. Locally advanced

National Comprehensive Cancer Network (NCCN) guidelines outline various radiological characteristics to define these categories [47] (Table 2).

However, the definitions of these three categories are not uniform as resectability varies based upon surgical experience and techniques. For example, one of the most commonly used definitions of borderline resectable pancreatic cancer (BRPC) includes nonmetastatic ca pancreas cases with venous involvement of the superior mesenteric vein or portal vein or gastroduodenal artery encasement up to the hepatic artery and/or tumor abutment of the superior mesenteric artery of less than or equal to 180°. In specialized centers, en bloc resection of the portal vein or superior mesenteric vein, or both, is commonly and safely practiced in the setting of borderline resectable tumors involving these veins [48]. However, abutment of a major artery such as the superior mesenteric artery often results in positive surgical margin

Table 2 Outcomes following >2100 Whipple resections, Tata Memorial Hospital (unpublished data)

(a, b & c, as per ISGPS definition)
***Period**: Period A: Routine use of preoperative biliary drainage, Period B: Standardization of pancreatic resections and anastomosis, Period C: Increasing volumes and refinement of surgical technique, Period D: Further increase in volumes, extended/vascular resection, use of neo-adjuvant Rx

after surgical resection and is presently not recommended [48–50].

The decision about surgical resection, however, should not be based on anatomic criteria alone. The biological behavior of the cancer and the patient's reserves to cope up with the physiological strain of a demanding surgery must be taken into consideration in the decision-making process. The recent International consensus on definition and criteria of BRPC has defined BRPC according to three distinct dimensions [51], viz. anatomical (A), biological (B), conditional (C):

- The anatomical criteria of BRPC: A tumor that is at high risk for margin positive resection (R1 or R2).
- The biological criteria of BRPC: Findings that raise the possibility (but not certainty) of extra-pancreatic metastatic disease (high serum CA 19-9 levels / radiologically suspected but unproven metastases).
- The conditional criteria of BRPC: High risk for morbidity or mortality post-surgery because of host-related factors including performance status and comorbidities.

These refinements should ensure standard reporting of outcomes ultimately resulting in establishment of the best possible management approach including use of neoadjuvant therapies for this unique subset of pancreatic cancers.

7.2 Surgical Techniques and Other Considerations

Surgical treatment for pancreatic cancer requires different procedures like pancreaticoduodenectomy, distal pancreatectomy with splenectomy, and total pancreatectomy depending on the site of tumor and extent of involvement of pancreas. Standard lymphadenectomy for pancreatoduodenectomy includes removal of lymph node stations 5, 6, 8a, 12b1, 12b2, 12c, 13a, 13b, 14a, 14b, 17a, and 17b [52]. After pancreaticoduodenectomy, pancreatic, biliary and gastric reconstruction is performed. Clinically relevant postoperative pancreatic fistula (CR-POPF) is the most troublesome complication after pancreatoduodenectomy. There has been a lot of debate regarding the technique used to do pancreatico-enteric anastomosis and development of CR-POPF. The most commonly used techniques include pancreaticojejunostomy (Fig. 3) and pancreaticogastrostomy [53]. Superiority of one of these techniques over another has not been proven and neither completely eliminate development of CR-POPF.

Survival advantage of extended resections including wide resections of the para-aortic lymph nodes and nerve plexus, and multi-visceral resections is not backed up by high level of evidence and hence these procedures are not recommended routinely [54–56]. These extended resections may lead to compromised quality of life like intractable diarrhea. However, in highly selected patients, with preserved performance status and stable or non-progressive disease on neoadjuvant treatment, extended resection can provide survival benefit over palliative care [57]. Radical surgery in presence of oligo-metastatic disease has also been reported with reported survival advantage in highly selected patients [58].

SMA first approach (six different approaches, Fig. 2) was proposed as a new modification of standard pancreaticoduodenectomy for improvement in margin positivity in borderline resectable pancreatic cancer [59]. A systematic review reported that the SMA first approach is associated with decreased blood loss, transfusion requirement, pancreatic

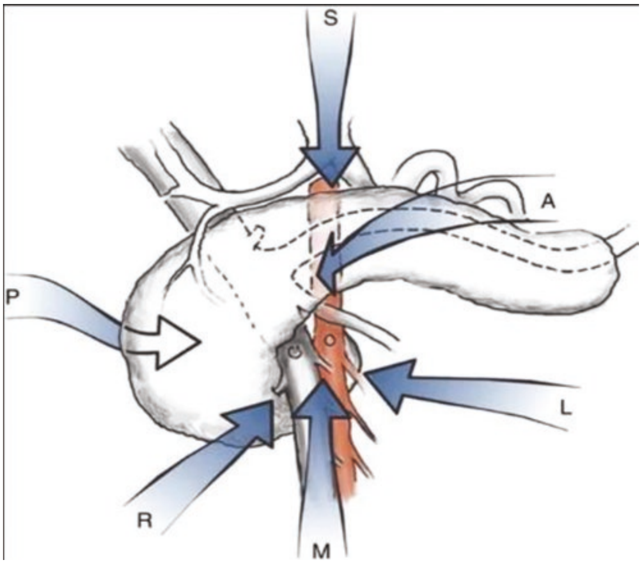

Fig. 2 Diagram showing six approaches to the superior mesenteric artery: *S* superior approach, *A* anterior approach, *P* posterior approach, *L* left posterior approach, *R* right/medial uncinate approach, *M* mesenteric approach

fistula rates, delayed gastric emptying, and lower local and metastatic recurrence rate [60, 61].

Laparoscopic approach in pancreatic cancer surgery is getting popular. Retrospective cohort studies have shown that laparoscopic distal pancreatectomy for cancer is non-inferior to open surgery in the context of overall survival. It is also beneficial to patients with an earlier return to diet and a shorter hospital stay [62]. The results from the recent LEOPARD-1 trial also show decreased recovery time without increasing overall complication rates and establish minimally invasive resection for body and tail of pancreas lesions as a preferable option [63]. By contrast, laparoscopic pancreaticoduodenectomy is complex and needs highly trained surgical skills. The generalized application of this technique remains questionable as seen with high morbidity and subsequent premature termination of LEOPARD-2 trial [64–66].

Hospital volume is arguably an important factor affecting mortality, complications, length of hospital stay, margin status, survival, and overall cost after pancreaticoduodenectomy [53, 67–69]. The complications and mortality largely depend on pancreatic anastomotic leak. Consistent practice of any standardized technique of anastomosis by an experienced surgeon helps in decreasing the rate of clinically relevant postoperative pancreatic fistula [53, 70]. Results of >2100 pancreaticoduodenectomies from Tata Memorial Hospital [71] also indicate the same (see Table 2). Therefore, it is recommended that pancreaticoduodenectomy should be done in specialized centers with experienced teams performing a large number (>15–20) of pancreatic resections per year [50].

8 Medical Management

8.1 Adjuvant Chemotherapy for Resected Pancreatic Cancer

The 5-year survival of pancreatic cancer patients undergoing surgery alone is 10-15% with median overall survival being 11-20 months. This has improved significantly with the use of adjuvant chemotherapy and has become standard of care. The results of ESPAC-01 trial showed that adjuvant chemotherapy with folinic acid (leucovorin) and fluorouracil was associated with better survival in patients with resected pancreatic cancer as compared with chemotherapy alone [72]. Another randomized trial, CONKO-001, comparing six cycles of adjuvant gemcitabine versus no adjuvant treatment after surgery found increased disease-free survival and overall survival in gemcitabine arm [73]. Further, ESPAC-04 trial which was a phase III randomized control trial comparing adjuvant gemcitabine versus combination of gemcitabine with capecitabine established combinational use as the superior regime for adjuvant therapy [74]. The recent PRIODIGE-24 trial showed a much superior median survival of 54.4 months with adjuvant modified FOLFIRINOX regimen as compared to 35 months with gemcitabine alone. The 3-year survival of 63.4% was seen in mFOLFIRINOX arm. The results of PRODIGE-24 made mFOLFRINOX the chemotherapy regimen of choice in patients with good performance status [75].

8.2 Neoadjuvant Chemotherapy/Radiotherapy

The role of neoadjuvant therapy has been investigated in many clinical trials in the USA, Europe, and Japan in order to achieve better local control and, ultimately, to improve survival of patients. Another important rationale for neoadjuvant therapy is better selection of patients who do not have the complications of aggressive disease or latent metastasis. Full-dose chemotherapy is better tolerated before surgery and preoperative therapy may be more effective than postoperative therapy because the resected tumor bed is associated with poor drug delivery and low sensitivity to chemotherapy and radiation due to poorly oxygenated tissues [76]. R0 resection rates are higher in BRPC after neoadjuvant therapy and survival of patients who undergo surgical resection is better than that of those who do not. Few small RCTs have shown benefit of neoadjuvant therapy in BRPC. A Korean phase II/III RCT by Jang et al. comparing neoadjuvant chemoradiation to upfront surgery in patients with BRPC. The intention-to-treat analysis of this study showed that the 2-year survival rate and median survival (40.7% and 21 months vs. 26.1% and 12 months) (hazard ratio 1.495, 95% CI [0.66, 3.36];

$p = 0.028$) were significantly better for patients with neoadjuvant therapy [77]. Recently published PREOPANC trial demonstrated significantly better overall survival in patients receiving gemcitabine-based chemoradiation as compared to upfront surgery group (35.2 months vs 19.8 months). The benefit was statistically significant in BRPC patients [78]. ALLIACE A21501 trial, a phase II trial evaluating mFOLFIRINOX in neoadjuvant setting showed median overall survival of 31 months with neoadjuvant therapy with no benefit of additional radiation. The results of this trial with extrapolation from experience of FOLFIRINOX has lead this regimen to be the most commonly used and effective chemotherapy regimen in neoadjuvant approach [79].

Neoadjuvant therapy is becoming increasingly popular due to high response rates and high R0 resection rates, and there is some evidence to recommend neoadjuvant therapies against upfront surgical resection in patients with BRPC. However, utility of neoadjuvant therapy in resectable pancreatic cancer continues to be a debated unanswered question [80]. Most of the clinical trials are limited due to lack of accrual, probably due to fear of loss of the opportunity of surgical resection [81].

8.3 First-Line Chemotherapy for Metastatic Pancreatic Cancer

Chemotherapy is the main line of treatment for metastatic pancreatic cancer. In a landmark clinical trial published in 1997, that compared gemcitabine and fluorouracil, median survival of 4.41 months and 5.65 months was seen in the fluorouracil group and gemcitabine group, respectively [82]. Since then, gemcitabine has been accepted as the standard chemotherapy.

In the phase 3 ACCORD-11 trial, the FOLFIRINOX regimen (oxaliplatin 85 mg/m^2, folinic acid [leucovorin] 400 mg/m^2, irinotecan 180 mg/m^2, bolus fluorouracil 400 mg/m^2, infusional fluorouracil 2400 mg/m^2 over 46 h, every 14 days) was shown to have better response, progression-free survival, and overall survival compared to gemcitabine for metastatic pancreatic cancer [83]. Although this is an attractive benefit, it has to be noted that FOLFIRINOX was associated with higher risk of febrile neutropenia, sensory neuropathy, and gastrointestinal toxicities. Hence, this regimen is recommended only for patients aged 75 years or younger with good performance status and without significant risk of cholestasis or cholangitis.

The MPACT trial, a phase III trial, showed that gemcitabine plus nanoparticle albumin bound paclitaxel (nab-paclitaxel) showed superior overall survival and progression-free survival to gemcitabine alone in metastatic pancreatic cancer patients [84]. The adverse effects of this regimen seem to be less severe than FOLFIRINOX. It can be used in a wider range of patients.

Finally, on the basis of current evidence, both FOLFIRINOX and gemcitabine plus nab-paclitaxel are the current regimens of choice for patients with good performance status. Gemcitabine plus erlotinib may be another option for patients who develop skin rash. Gemcitabine monotherapy should be used in patients with compromised performance status.

8.4 Second-Line Chemotherapy for Metastatic Pancreatic Cancer

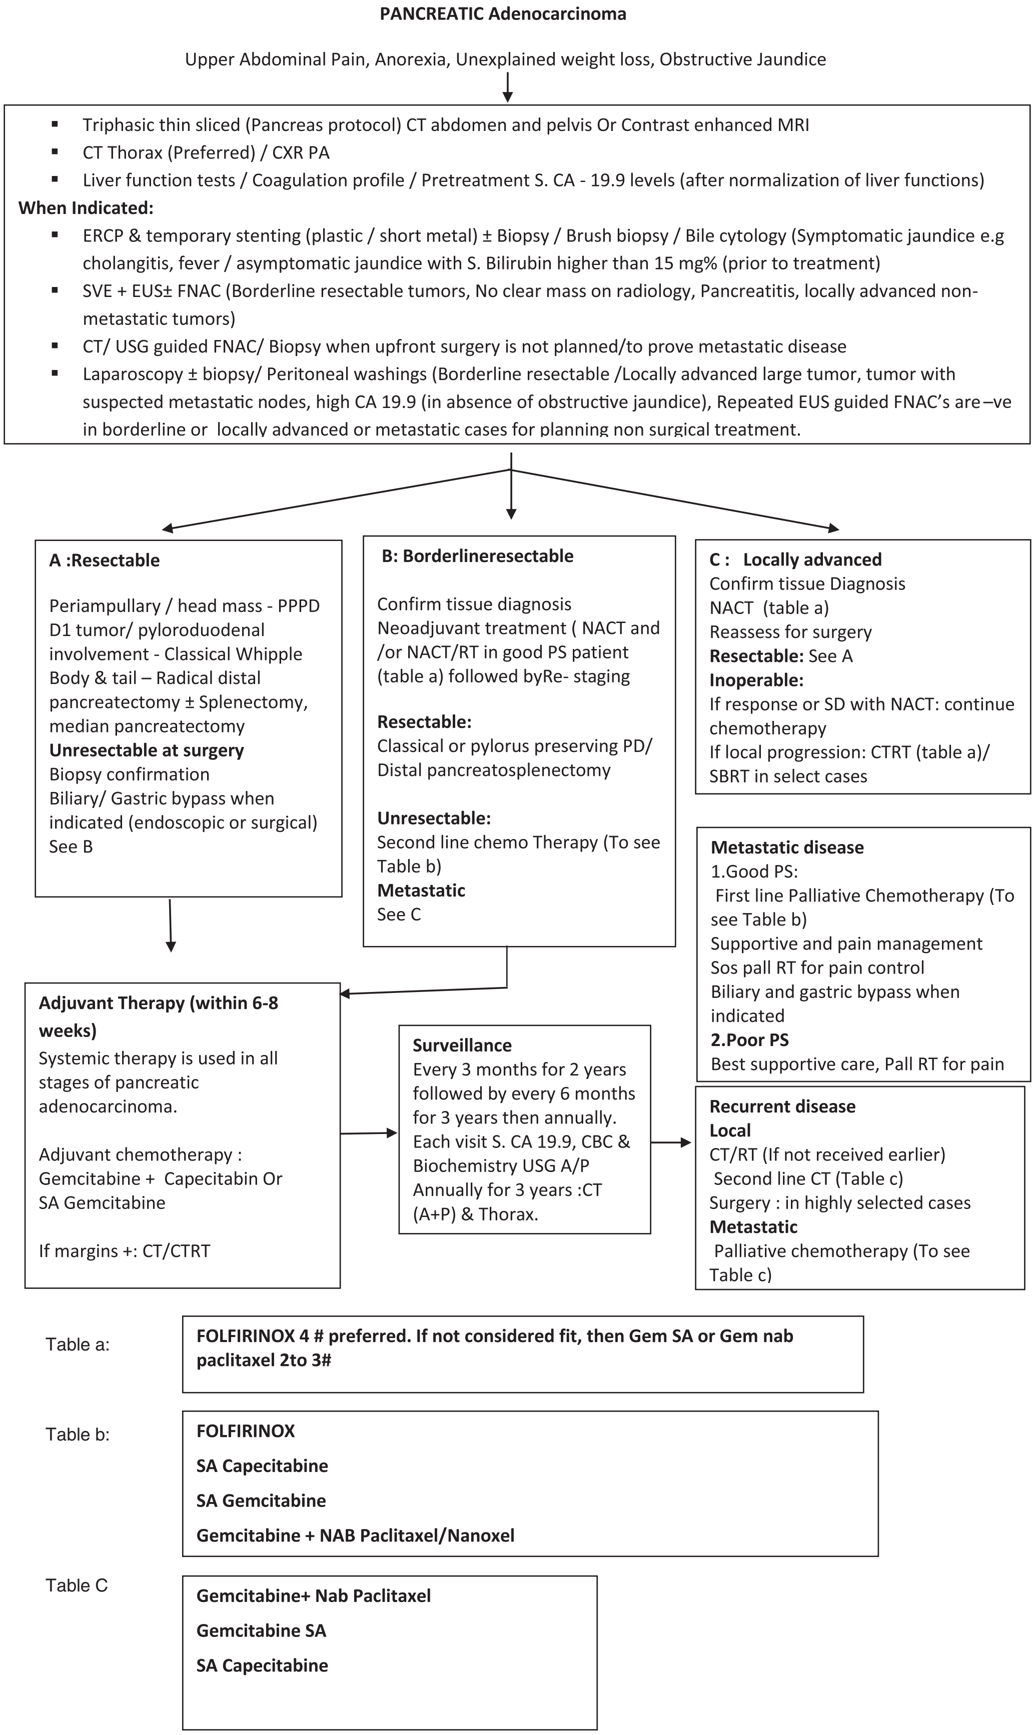
After progression with first-line chemotherapy, second-line chemotherapy should be considered in patients with good performance status as there is some benefit [85], although there is no established evidence regarding the regimen of second-line chemotherapy.

9 Radiotherapy

Radiotherapy is used with chemotherapy for pancreatic cancer in adjuvant or definitive settings, or as neoadjuvant approach as discussed in the previous section.

There have been increasing reports showing improvement in margin negative R0 resections with neoadjuvant approach using chemoradiation [86]. Stereotactic body radiation therapy (SBRT) and intensity-modulated radiation therapy (IMRT) are proven to be safe and effective in neoadjuvant [87] and palliative settings.

The role of definitive chemoradiation therapy for locally advanced pancreatic cancer has been intensively studied. However, the survival benefits of chemoradiation therapy remain a hotly debated topic [88]. The ECOG 4201 trial compared chemoradiotherapy with chemotherapy in patients with locally advanced pancreatic cancer. The median survival was 9.2 months for chemotherapy in gemcitabine arm compared to 11.1 months in chemoradiotherapy arm. However, due to small number of recruited patients, the study could not reach any definitive conclusions [89]. A randomized study comparing chemoradiation therapy and chemotherapy after 4 months of gemcitabine with or without erlotinib (LAP 07) showed chemoradiation was not superior to chemotherapy locally advanced pancreatic cancer [90]. Further studies are required to establish the potential survival advantages of chemoradiation therapy in these locally advanced tumors. A management algorithm for pancreatic adenocarcinoma is presented in Fig. 3.



PANCREATIC Adenocarcinoma

Upper Abdominal Pain, Anorexia, Unexplained weight loss, Obstructive Jaundice

- Triphasic thin sliced (Pancreas protocol) CT abdomen and pelvis Or Contrast enhanced MRI
- CT Thorax (Preferred) / CXR PA
- Liver function tests / Coagulation profile / Pretreatment S. CA - 19.9 levels (after normalization of liver functions)

When Indicated:

- ERCP & temporary stenting (plastic / short metal) ± Biopsy / Brush biopsy / Bile cytology (Symptomatic jaundice e.g cholangitis, fever / asymptomatic jaundice with S. Bilirubin higher than 15 mg% (prior to treatment)
- SVE + EUS± FNAC (Borderline resectable tumors, No clear mass on radiology, Pancreatitis, locally advanced non-metastatic tumors)
- CT/ USG guided FNAC/ Biopsy when upfront surgery is not planned/to prove metastatic disease
- Laparoscopy ± biopsy/ Peritoneal washings (Borderline resectable /Locally advanced large tumor, tumor with suspected metastatic nodes, high CA 19.9 (in absence of obstructive jaundice), Repeated EUS guided FNAC's are –ve in borderline or locally advanced or metastatic cases for planning non surgical treatment.

A :Resectable

Periampullary / head mass - PPPD
D1 tumor/ pyloroduodenal involvement - Classical Whipple
Body & tail – Radical distal pancreatectomy ± Splenectomy, median pancreatectomy
Unresectable at surgery
Biopsy confirmation
Biliary/ Gastric bypass when indicated (endoscopic or surgical)
See B

B: Borderlineresectable

Confirm tissue diagnosis
Neoadjuvant treatment (NACT and /or NACT/RT in good PS patient (table a) followed byRe- staging

Resectable:
Classical or pylorus preserving PD/ Distal pancreatosplenectomy

Unresectable:
Second line chemo Therapy (To see Table b)
Metastatic
See C

C : Locally advanced
Confirm tissue Diagnosis
NACT (table a)
Reassess for surgery
Resectable: See A
Inoperable:
If response or SD with NACT: continue chemotherapy
If local progression: CTRT (table a)/ SBRT in select cases

Metastatic disease
1.Good PS:
First line Palliative Chemotherapy (To see Table b)
Supportive and pain management
Sos pall RT for pain control
Biliary and gastric bypass when indicated
2.Poor PS
Best supportive care, Pall RT for pain

Adjuvant Therapy (within 6-8 weeks)
Systemic therapy is used in all stages of pancreatic adenocarcinoma.

Adjuvant chemotherapy :
Gemcitabine + Capecitabin Or
SA Gemcitabine

If margins +: CT/CTRT

Surveillance
Every 3 months for 2 years followed by every 6 months for 3 years then annually.
Each visit S. CA 19.9, CBC & Biochemistry USG A/P
Annually for 3 years :CT (A+P) & Thorax.

Recurrent disease
Local
CT/RT (If not received earlier)
Second line CT (Table c)
Surgery : in highly selected cases
Metastatic
Palliative chemotherapy (To see Table c)

Table a:

FOLFIRINOX 4 # preferred. If not considered fit, then Gem SA or Gem nab paclitaxel 2to 3#

FOLFIRINOX
SA Capecitabine
SA Gemcitabine
Gemcitabine + NAB Paclitaxel/Nanoxel

Table C

Gemcitabine+ Nab Paclitaxel
Gemcitabine SA
SA Capecitabine

Fig. 3 Management algorithm

10 Prognosis

As discussed above, majority of patients with pancreatic cancer die of their disease, even after complete resection. The most important prognostic factor for patients undergoing R0 resection is nodal status. Five-year survival after surgery is approximately 10% for node-positive disease [91], while it is approximately 30% for node-negative disease [92]. In addition to stage, the status of the surgical margins (involved or uninvolved), tumor differentiation, presence or absence of lymphatic and peri-neural invasion, and both preoperative and postoperative serum CA 19-9 levels are important factors affecting survival in pancreatic ductal adenocarcinoma [93–95]. The median overall survival for untreated, locally advanced, unresectable pancreatic cancer is 8–12 months which decreases to only 3–6 months for metastatic cancer at presentation. In these patients, current chemotherapy regimens with FOLFIRINOX, the median survival has been shown to be extended in the range of 15–18 months in advanced disease [96].

11 Palliative Management in Advanced Metastatic Disease

Palliative care is equally important as other therapies, and pancreatic cancer patients will require some form of palliation at some point in disease course. These patients usually develop obstructive jaundice and gastric outlet obstruction requiring surgical, endoscopic, or radiological interventions. Technologic improvements have led to replacement of percutaneous biliary drainage by endoscopic stenting in most cases. Large diameter metal stents are preferred over small caliber plastic stents because of the longer patency time and lower incidence of cholangitis [97]. Surgical gastrojejunostomy and endoscopic duodenal stents are feasible options for palliation of gastric outlet obstruction. Endoluminal duodenal stents are especially preferred when life expectancy is limited or in patients with poor performance status.

Pain is a significant debilitating feature of advanced pancreatic cancer, and all patients should receive assessment for the level of pain and degree of pain relief from analgesics at every clinic visit. The backbone of pain management is typically opioid medication, and pain relief is often successfully achieved by opioid analgesics alone. Patients with intractable pain refractory to other medication are managed by inhibition of synaptic pathways within the celiac plexus without nerve destruction (i.e., celiac plexus block using a bolus injection of local anesthetic) or chemical destruction using dehydrated alcohol (celiac plexus neurolysis).

CT	Carney's triad
CT	Computerized tomography
DOG1	Discovered on GIST1
GIST	Gastrointestinal stromal tumours
ICC	Interstitial cells of Cajal
IHC	Immunohistochemistry
IM	Imatinib mesylate
MRI	Magnetic resonance imaging
PDGFRA	Platelet-derived growth factor receptor α
PET	Positron-emission tomography
PFS	Progression-free survival
SDH	Succinate dehydrogenase
SMT	Submucosal tumours

1 Introduction

Gastrointestinal stromal tumours (GIST) are rare mesenchymal tumours of the gastrointestinal tract, though rarely arising from intra-abdominal soft tissues [1]. They are most commonly seen in stomach (60%) and small intestine (30%) and less commonly in the rectum and omentum [2, 3]. GISTs are either derived from or differentiated towards interstitial cells of Cajal (ICC) (which act as the 'pacemaker' cells of the gastrointestinal tract) or their stem cell precursors [4].

GISTs have often been clubbed together with other smooth muscle neoplasms, though the idea that they were a different set of tumours was proposed as early as the 1980s [5]. The discovery of the c-KIT gene (cellular homologue of the oncogene v-KIT) has led to the recognition of GIST as a separate disease entity [6, 7].

2 Global Incidence, Epidemiology, and Clinical Presentation: Global and India

GISTs are rare diseases, but available data does suggest variances in incidence across geographical regions [8]. They are most commonly seen beyond the age of 50 years (median age—63 years), though they are seen across age-groups as well. There is limited data from India with regard to presentation and incidence [9, 10]. GISTs are rare in the paediatric age group, but are noted in the second decade with a female predilection. They almost exclusively arise in the stomach with frequent nodal involvement in this age-group, though nodal involvement is rarely seen in adults GISTs as well [11].

Approximately 18–25% of patients have GIST are incidentally diagnosed. The most common sites include stomach (60%), jejunum and ileum (30%), duodenum (5%), and colon/rectum (4%).The most common symptomatic presentation (75% of patients) is that of a lump or palpable growth [12]. Occasionally, they may present with emergent complications like an obstruction, bleeding, rupture of tumour, or bowel perforation. Due to increased awareness of GIST as an entity, a new subgroup of GISTs called mini-GISTs (measuring between 1 and 2 cm) and micro-GISTs (measuring <1 cm) are now part of the diagnosed disease spectrum [13].

3 Molecular Basis of GIST

The KIT and platelet-derived growth factor receptor α (PDGFRA) genes are central in understanding the pathogenesis of GIST and its malignant potential [14]. Mutations in the KIT (70%; commonly in exon 11 and less commonly in exon 9) and PDGFRA (10%; exon 18 and exon 14) genes result in constitutive activation and signalling (in the absence of the endogenous ligand) causing a chain of cellular events leading to the advent of GIST [1, 15]. Mutations in the exon 11 themselves are a heterogeneous group, with different mutations having different biological behaviours [16–18]. GISTs with PDGFRA mutations are possibly less aggressive compared to KIT mutant GISTs. Though 10% of all GISTS are KIT and PDGFRA 'wild', next-generation sequencing in this 'wild type' cohort has identified mutations involving succinate dehydrogenase (SDH) as well as BRAF genes [19]. Patients with SDH deficiencies are usually younger with near universal involvement of the stomach as primary site of GIST. The mutations described, besides being central to the etiopathogenesis of GIST have an increasingly important bearing on the treatment modalities used in GIST.

4 Evaluation and Work-Up

GISTs may often be diagnosed incidentally, though a complete diagnostic evaluation is required for confirmation and staging.

4.1 Endoscopy and Endoscopic Ultrasound (EUS)

The initial investigation for small-sized GISTs would be an EUS—FNA/FNB [20]. EUS-FNA is indicated for lesions measuring >1 cm (usually between 1 and 2 cm) that are suspected to be potentially malignant [21]. An endoscopy is preferred for larger tumours in terms of adequate evaluation as well as taking adequate biopsies.

4.2 Radiology and Nuclear Imaging

A contrast-enhanced computerized tomographic (CECT) scan is the imaging modality of choice for accurate detection and staging of a GIST [22]. In uncommon situations such as in the case of anorectal GISTs, a magnetic resonance imaging (MRI) may provide additional information above and beyond a CECT scan.

Positron-emission tomography (PET) provides functional information that may help in staging, especially when combined with morphological information provided by a CT. A PET/CT is valuable especially in differentiating necrotic tissue from viable tissue, recurrent tumour from scar tissue, and in assessing response post-therapy in GISTs [23]. The Choi criteria, which are a combination of tumour density (15% change) and modified tumour size (>10%), are validated criteria for early response evaluation, but is yet to be routinely used. [24].

4.3 Pathology

- Gross pathology: GISTs are usually well-circumscribed or multinodular tumours that may develop in any portion of the gut wall, but most are centred in the submucosa or the muscularis propria. Cut sections identify grey white, solid tumours, with a fleshy appearance and often show haemorrhage, necrosis, or cystic change [25].
- Microscopic features: Gastrointestinal stromal tumours are cellular lesions, with 70% of cases composed of spindle cells, 20% of epithelioid cells, and the remainder having a mixed cellular composition. Tumour size and mitotic count per 50 HPF are regarded as the best predictor of malignant behaviour in GIST. [26].
- Immunohistochemistry (IHC): On IHC, KIT (CD117) expression is a sensitive and specific marker for GIST, with about 95% of GISTs showing a strong and diffuse cytoplasmic staining for KIT, although some tumours, (e.g. epithelioid morphology), can show membranous staining [27]. Although CD117 is a highly sensitive marker of GIST, it can be consistently expressed in many other tumours, e.g. seminomas, mastocytomas, melanomas, clear cell sarcomas, etc. [28]. DOG1 (Discovered on GIST1) is a commonly used IHC marker along with KIT for the diagnosis of GIST [29]. The sensitivity of KIT and DOG1 is individually approximately 95% for the diagnosis of GIST. Approximately, one-third of KIT-negative GIST stain with DOG1, thereby making it a useful adjunct in the diagnosis of GIST [30]. Other IHC markers which stain positively in GIST include CD34, caldesmon, smooth muscle actin, desmin, S-100 protein, and keratin.
- Although GISTs are the most common mesenchymal tumour of the GI tract, the differential diagnosis includes other tumours in this location, including smooth muscle tumours, nerve sheath tumours, fibromatoses, etc.

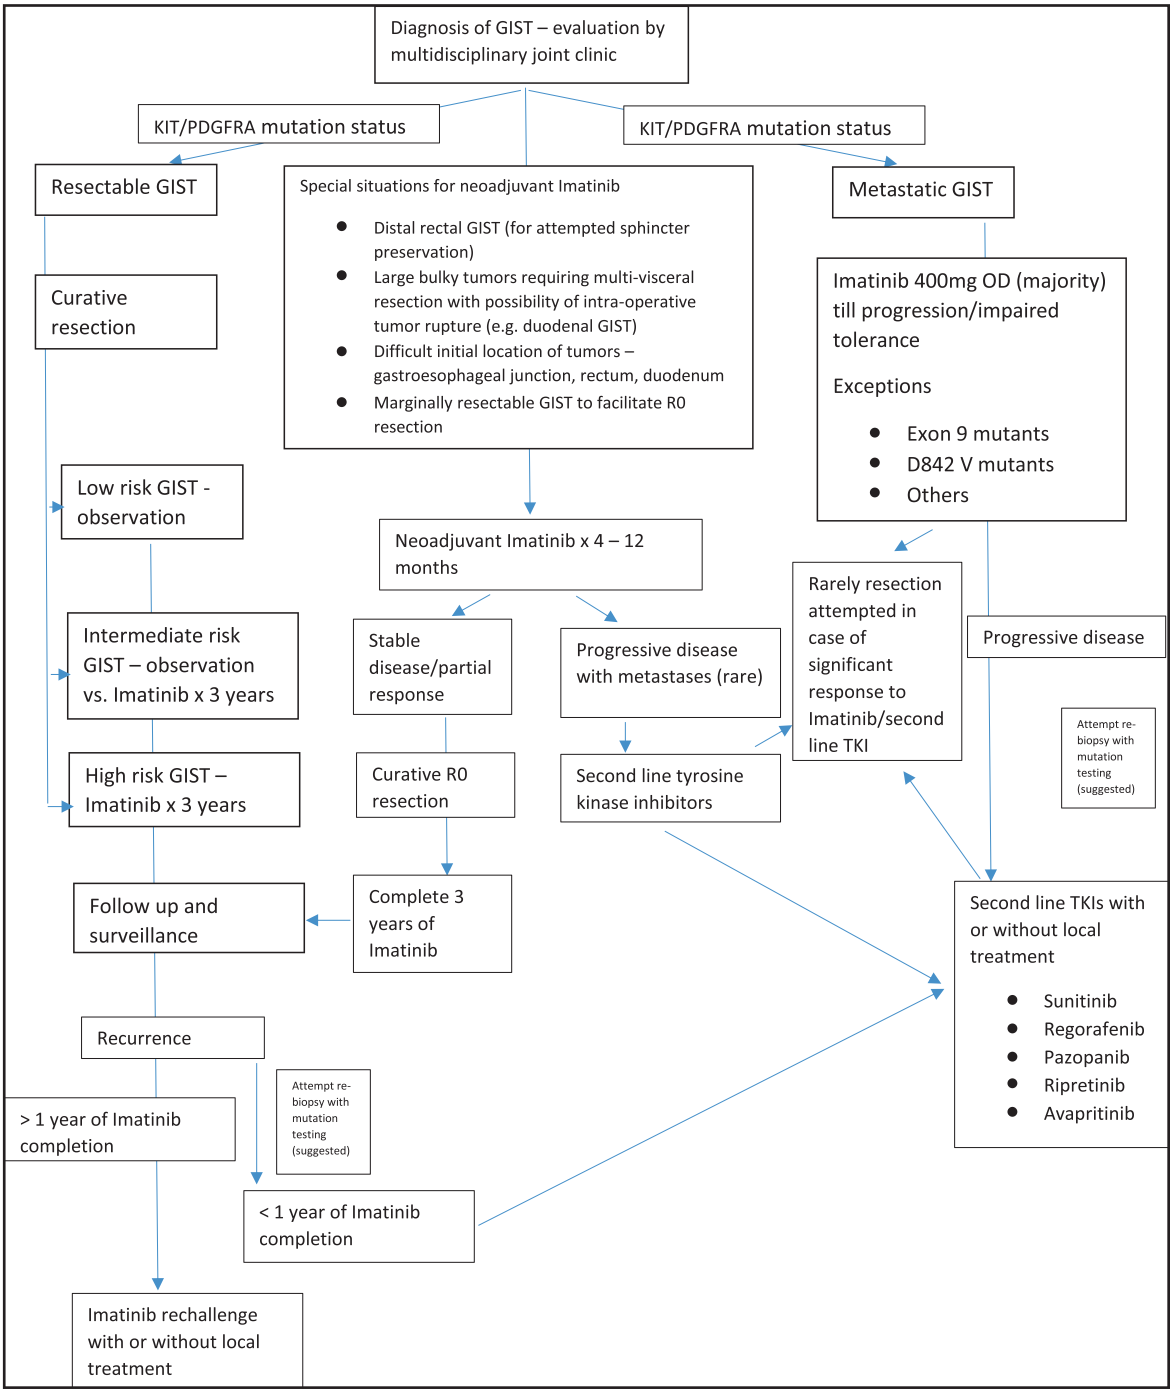
5 Principles of Management (Overview)

The management of GIST is based on tumour prognosis and staging once the diagnosis is confirmed. A number of prognostic classification systems have developed over the last two decades for GIST [30–33]. Table 1 offers a snapshot of the widely used system as proposed by Miettinen [26, 34]. Comparative studies of these classifications suggest that while all of them distinguished well in terms of high-risk and low-risk tumours, there was significant heterogeneity in the high-risk groups and more importantly, no significant differences in overall survival between the risk groups [35]. These classifications also do not take into cognizance the relevance of KIT mutation status in their risk assessment.

Once the stage is identified, patients in TMH are treated along the algorithm shown in Fig. 1.

Table 1 Rates of progression-free survival for gastrointestinal stromal tumours (GISTs) of stomach, small intestine, and rectum as per Miettinen's classification

Tumour size (cm)	Mitotic rate (HPFs)	Gastric	Jejunum/ileum	Duodenum	Rectum
≤2	≤5/50	100	100	100	100
2–5	≤5/50	98.1	95.7	91.7	91.5
5–10	≤5/50	96.4	76	66	43
>10	≤5/50	88	48		
≤2	>5/50	100	50	–	46
2–5	>5/50	84	27	50	48
5–10	>5/50	45	15	14	29
10	>5/50	14	10		



Diagnosis of GIST – evaluation by multidisciplinary joint clinic
KIT/PDGFRA mutation status
KIT/PDGFRA mutation status
Resectable GIST
Special situations for neoadjuvant Imatinib
Distal rectal GIST (for attempted sphincter preservation)
Large bulky tumors requiring multi-visceral resection with possibility of intra-operative tumor rupture (e.g. duodenal GIST)
Difficult initial location of tumors – gastroesophageal junction, rectum, duodenum
Marginally resectable GIST to facilitate R0 resection
Metastatic GIST
Curative resection
Imatinib 400mg OD (majority) till progression/impaired tolerance
Exceptions
Exon 9 mutants
D842 V mutants
Others
Low risk GIST - observation
Neoadjuvant Imatinib x 4 – 12 months
Rarely resection attempted in case of significant response to Imatinib/second line TKI
Intermediate risk GIST – observation vs. Imatinib x 3 years
Stable disease/partial response
Progressive disease with metastases (rare)
Progressive disease
Attempt re-biopsy with mutation testing (suggested)
High risk GIST – Imatinib x 3 years
Curative R0 resection
Second line tyrosine kinase inhibitors
Follow up and surveillance
Complete 3 years of Imatinib
Second line TKIs with or without local treatment
Sunitinib
Regorafenib
Pazopanib
Ripretinib
Avapritinib
Recurrence
> 1 year of Imatinib completion
Attempt re-biopsy with mutation testing (suggested)
< 1 year of Imatinib completion
Imatinib rechallenge with or without local treatment

Fig. 1 Management of GIST. Stage-wise management algorithm followed in TMH

6 Surgical Management

6.1 General Principles

Surgery is the primary treatment of choice for patients with localized or potentially resectable GIST lesions. Patients with resectable GIST may not require a preoperative biopsy, though every attempt should be made to obtain a biopsy in case of diagnostic dilemmas. A biopsy should be obtained in case neoadjuvant IM is being planned prior to attempted resection.

The surgical procedure aims at resecting the tumour with histologically negative margins (R0 resection), with segmental or wedge resections often being adequate. On laparotomy/laparoscopy, the abdomen should be thoroughly explored to evaluate peritoneal metastatic deposits. Primary GISTs may demonstrate inflammatory adhesions to surrounding organs, though true invasion is infrequent. GISTs are fragile tumours and should be carefully handled during resection to avoid tumour rupture. The goal is to achieve complete gross resection of the tumour with an intact pseudo capsule [36].

Lymphadenectomy is not indicated unless enlarged or pathologic nodes are seen on imaging or intraoperatively as GISTs rarely spread to regional nodes. Available evidence suggests that patients undergoing R0 or R1 resections have a similar prognosis, while patients with R2 resections have inferior outcomes [37]. The presence of microscopically positive margins (R1) after macroscopic total resection may not confer a worse prognosis. This is based on data from North America in more than 800 patients where there was no difference in recurrence-free survival in those who had R1 versus R0 resection [38].

6.2 Extent of Surgical Resection

Complete resection with at least a 1- to 2-cm gross margin should be the goal of surgical treatment.

Unlike other gastric tumours, gastric GISTs, usually require only a partial gastrectomy or even gastric wedge resection to achieve these margins. There is no oncological benefit in performing a total gastrectomy over a partial gastrectomy in gastric GISTs.

6.3 Minimally Invasive Approaches

Minimally invasive resection and open techniques are comparable in their outcomes in gastric GISTs. A meta-analysis of 19 studies ($n = 1060$ GIST cases) revealed no difference in long-term outcomes of GIST resections using laparotomy and laparoscopy. Laparoscopic resection in GISTs is also an acceptable standard of surgery [39–43]. Current guidelines prefer open surgeries for tumours greater than 5 cm in diameter. Unique to laparoscopic resections of GIST is the removal of the specimen within a closed system, such as a retrieval bag to avoid tumour spillage or seeding of port sites.

Three distinct minimally invasive approaches to resecting gastric GISTs based on tumour location in the stomach have been described and act as a basis for deciding the approach and extent of resection in these tumours [44].

6.4 Management of Small GISTs

GISTs ≥2 cm in size should be considered for resected, while there is equipoise on the management of tumours less than 2 cm in size. Endoscopic Mucosal Resection (EMR)And submucosal dissection (ESD) techniques can be occasionally employed in the management of few small GISTs. Gastric GISTs that are less than 2 cm in diameter and asymptomatic are currently referred to as very small, mini- (1–2 cm), or micro- (<1 cm) GISTs. Such tumours generally demonstrate benign clinical behaviour. However, lesions with high-risk features on EUS (irregular borders, cystic spaces, ulceration, echogenic foci, and internal heterogeneity) need adequate addressal due to their risks of progression. Current recommendations include initial evaluation with EUS for micro-GISTs, while EUS with or without CT is recommended for mini-GISTs. Subsequent follow-up is performed with serial EUS [45].

Surgery is required for lesions with high-risk features or those that increase in size on follow-up imaging.

6.5 Neoadjuvant Imatinib

Large abdominal tumours with a significant risk of tumour rupture during surgery are considered for treatment with preoperative IM. Tumours requiring complex surgical procedures or multivisceral resections are also considered for neoadjuvant IM after a multidisciplinary assessment [46–48].

The duration of preoperative medical therapy varies from 3 months to 1 year. Further detailing with regard to neoadjuvant imatinib therapy is mentioned in the medical management section of the chapter.

6.6 Unresectable, Recurrent, or Metastatic GIST

Surgery is rarely indicated in patients with metastatic GIST:

- Limited disease progression refractory to imatinib
- Initially unresectable tumours after a favourable response to imatinib.

- Management of symptomatic bleeding, obstruction, or similar local tumour-related complication.
- Liver limited metastatic disease where complete resection of disease can be achieved.

7 Medical Management

7.1 Brief History

The initial medical management of GIST is based on the role of imatinib mesylate (IM), a selective tyrosine kinase inhibitor of KIT, PDGFRA, and ABL. The significant response of a heavily pre-treated patient with GIST to IM followed by multiple trials highlighting responses and improved survivals with IM in GIST have ensured that IM is usually the first line of management in patients requiring systemic treatment [49].

7.2 Adjuvant Treatment Post Resection of GIST

The treatment of GIST post resection is assessed by the risk recurrence and prognostic scores previously discussed. Patients with very low-risk disease should be kept under surveillance/observation with no requirement of further treatment.

For patients with intermediate-risk GIST (recurrence risk 10–24%), adjuvant IM may or may not be considered [50–52]. However, there is a trend towards treating these patients with adjuvant IM for 3 years.

The evidence for the adjuvant treatment of resected GIST with IM was based on the ACOSOG Z9000 (Alliance) intergroup phase 2 trial. Patients labelled as ‘high risk’ tumours, (tumour diameter > 10 cm, intraperitoneal tumour rupture, or up to 4 peritoneal implants) received 1 year of adjuvant IM and showed improved 1-, 3-, and 5-year OS rate was 99, 97, and 83%, as compared to historical controls [53].The current standard of 3 years of adjuvant IM is based on the SSG XVIII Phase III trial, which showed that 3 years of adjuvant IM improved recurrence-free survival when compared to 1 year of adjuvant IM (65.6% vs. 47.9%; $p < 0.001$) [54]. A greater benefit with 3 years of IM was seen in patients with exon 11 mutations than other mutations, underscoring the importance of mutation testing in GIST [55]. Studies evaluating along duration of adjuvant IM are also being evaluated [51, 56].

The importance of mutation testing is also important in two specific scenarios. Firstly, GISTs harbouring the PDGFRA Exon 18/ D842V mutation (comprising 60–70% of PDGFRA mutants) are considered relatively resistant to IM and are considered for observation alone in these subgroup of patients [52, 57, 58]. Additionally, in KIT exon 9 mutants it may be worthwhile considering 800 mg/day as adjuvant therapy (based on the increased dose showing superior outcomes for this subset of tumours in the advanced setting) [52, 59].

7.3 Neoadjuvant Imatinib in GIST

Specific indications for the use of neoadjuvant IM are yet to standardized, but some scenarios where a neoadjuvant approach with IM is considered include:

- Anorectal GIST—for organ and/or sphincter preservation.
- Bulky GISTs in the duodenal-pancreatic region to reduce the extent of multivisceral resections and avoid intra-operative tumour rupture.
- Gastroesophageal junction, rectum, and duodenum GISTs where surgical access to tumours is difficult.
- Marginally resectable GIST to facilitate R0 resection.

Pooled data from the EORTC STBSG sarcoma group, in patients receiving neoadjuvant IM, showed that 83.2% of patients underwent R0 resection. Patients had received neoadjuvant IM for a period of 4–12 months [60]. The feasibility of neoadjuvant IM has also been shown with retrospective studies from Tata Memorial Hospital [48, 61].The Apollon phase II study prospectively evaluated the performance of neoadjuvant IM and showed high R0 resection rates and high PFS rates (3 year PFS—85.2%) [62]. Similar resection rates and survivals have been shown in other prospective studies as well [63].

The use of neoadjuvant IM has clinical implications in selective cases of GIST, though many questions in terms of duration of neoadjuvant IM, duration of adjuvant IM when neoadjuvant IM has been used and use of a higher dose in KIT exon 9 mutants remain to be answered [48].

7.4 Treatment of Advanced/Metastatic GIST

Patients with advanced/metastatic GIST have prolonged median survivals despite potentially advanced nature of disease. Patients with advanced GIST should have a KIT mutation testing and if required PDGFRA analysis while being planned for treatment.

The initial treatment for advanced/metastatic GIST is IM, with a dose of 400 mg/day recommended for KIT exon 11 mutants and 800 mg/day for KIT exon 9 mutants. This is based on patients with KIT exon 9 mutants deriving a PFS benefit when treated with 800 mg/day dosing [64]. Most patients respond to IM in a median of 3 months, though slower rate of responses is also known. The Choi criteria using PET scans can also be used for response assessment in GISTs [65].

Treatment with IM should be considered till progression, issues with tolerance, or patient choice [13]. The median progression-free survival with first-line IM in older series is approximately 18–24 months, though more recent series have shown an increased PFS of up to 3 years [10, 19, 60, 66, 67]. These differences can be explained by imatinib being used upfront current era and smaller tumours at diagnosis . There is also a select cohort of patients who will remain progression free for 6–10 years on IM alone [68].

Most patients with advanced GIST (approximately 80%) will progress after a median of 2–3 years, primarily due to the development of secondary KIT mutations [69]. Secondary mutations typically occur in the ATP binding pocket of KIT encoded by exons 13 and 14, and the activation loop (A-loop) encoded by exons 17 and 18 [70]. There is some evidence to suggest mutation status on progression may help guide second-line treatment options, i.e. sunitinib in KIT exon 13/14 mutant GISTs and regorafenib in secondary exon 17 mutants [71, 72].

Options post progression with IM include TKIs like sunitinib and regorafenib. Sunitinib (an oral multitargeted receptor tyrosine kinase inhibitor targeting KIT, PDGFRs, VEGFR-1, VEGFR-2, VEGFR-3, FLT3 and RET) has been shown to improve median time to progression as compared to placebo in the second line setting (27.3 weeks vs. 6.4 weeks; $p < 0.0001$) in a randomized setting and is currently recommended for the same [73]. Treatment with sunitinib requires monitoring, as there is an increased incidence of fatigue, diarrhoea, skin discolouration, and nausea seen with sunitinib. In patients who have progressed on both imatinib and sunitinib, the recommended option for further treatment is regorafenib (oral multikinase inhibitor inhibiting VEGFR1–3, TEK), KIT, RET, RAF1, BRAF, $\text{BRAF}^{\text{V600E}}$, PDGFR, and FGFR). The GRID study showed an improvement in PFS when regorafenib was compared to placebo (4.8 months vs. 0.9 months; $p < 0.0001$). The most common regorafenib-related adverse events of grade 3 or higher seen in the study were hypertension, hand-foot skin reaction, and diarrhoea, and these not to be kept a watch for.

While sequencing of treatment as mentioned above is preferable, options beyond this paradigm also need exploration. A commonly used treatment modality is increased dosing of IM from 400 mg to 800 mg per day [74]. Another strategy is evaluation of metastasectomy or resection in patients with limited progression [75, 76].

Sorafenib, dasatinib, and pazopanib have also shown limited activity in patients with advanced GIST [77–81].

7.5 Radiation Management

GIST is traditionally considered a radio resistant tumour [82]. Radiotherapy has shown to effect durable stabilization of the target lesions in some studies [83]. A few scenarios where radiotherapy may be attempted include [84]:

- Radiotherapy of metastases for palliation
- Radiotherapy of focally progressing lesions
- Definitive radiotherapy as an alternative to surgery in localized gist in elderly patients not feasible for surgery

8 Special Situations in GIST

8.1 Syndromes Associated with GIST

GIST is a predominantly sporadic disease, but germline mutations with familial predisposition to GIST have been identified [85, 86].

- Neurofibromatosis type 1; von Recklinghausen's disease (NF1): NF1 is an autosomal dominant hereditary disorder, with the mutated NF1 protein encoding the GTPase activating protein, neurofibromin. Approximately 34% of GI tract malignancies in patients with NF1 were GISTs. GISTs associated with NF1 have neither KIT nor PDGFRA mutations [87]. These tumours classically do not respond well to IM.
- Carney-Stratakis syndrome (CSS): CSS is an autosomal dominant syndrome with incomplete penetrance characterized by the development of paraganglioma, GIST, or both. Patients usually have mutations in succinic dehydrogenase (SDH)-B, C, and –D, with no mutations in KIT or PDGFRA.
- Carney's triad (CT): Carney's triad is a non-hereditary syndrome comprising paraganglioma, GIST, and pulmonary chordomas (atleast two of the three manifestations) [88]. These tumours do not have mutations in SDH, but have deletions of chromosome 1p and 1q12-q21, the site of the SDH-C gene. Mutations commonly associated with sporadic GIST are not found in these tumours. Tumours associated with CT are commonly seen in younger women, with frequent lymph node metastases, and multifocality.

Though the evidence is sparse, GISTs associated with the above-mentioned hereditary syndromes are generally less sensitive to treatment with IM [86].

8.2 Treatment of Advanced GIST with PDGFRA Mutations

Patients with PDGFRA mutations are seen in 5–15% localized GISTs, and 1–3% of advanced GISTs [89, 90]. Patients with resected disease and harbouring PDGFRA D842V mutations are considered for observation only. Evidence on these relative rare subsets comes from retrospective studies. The combined data from the European Organisation for Research and Treatment of Cancer (EORTC), Soft Tissue and Bone Sarcoma Group (STBSG), French Sarcoma Group (GSF-GETO), the Italian Sarcoma Group (ISG), and the Spanish Sarcoma Groups (GEIS) showed that patients harbouring the *PDGFRA-D842V* substitutions did not have responses to IM while those with other *PGFRA* mutations had responses to IM [91]. This also translated into markedly differing survivals between the two mutant cohorts. A second study from the Dutch group and North America, in contrast, suggested that a small cohort of patients with D842V mutants do respond to IM, though such patients would need frequent monitoring if started on IM [92]. A majority of patients with PDGFRA non-D842V respond to and should be treated with IM, while for patients with D842V mutations, the appropriate line of management at this juncture is still to be elucidated. Avapritinib is a relatively new drug that has shown encouraging results against all PDFGRA mutations and is to be considered in this setting.

9 Stage-Wise Prognosis with Current Management

The use of improved surgical techniques, early diagnosis of GIST, and systemic treatment with IM and other TKIs has improved survival across stages of GIST. The expected survival for patients receiving multimodality management in the current era is detailed in Table 2.

Table 2 Expected survival for patients receiving multimodality management

Stage	5-year overall survival (%) [90]
Low-risk and intermediate-risk resected GIST	91%
High-risk resected GIST	74%
Metastatic GIST	48%

and Amit Joshi

Abbreviations

CNS	Central nervous system
CT	Computed tomography
HIFU	High-intensity focused ultrasonic ablation
LDH	Lactate dehydrogenase
MRI	Magnetic resonance imaging
nccRCC	Nonclear cell RCC
NSS	Nephron-sparing surgery
PFS	Progression-free survival
RCC	Renal cell carcinoma
RFA	Radiofrequency ablation
RN	Radical nephrectomy
TKI	Tyrosine kinase inhibitors
ULN	Upper limit of normal
USG	Ultrasonography
VEGF	Vascular endothelial growth factor

1 Introduction

Renal cell carcinoma (RCC) is an aggressive malignancy that comprises approximately 3% of all adult cancers, with a median age of 64 years at diagnosis. RCC accounts for 90% of renal tumors, with clear cell carcinoma being the most common histology [1, 2]. In contrast to developed countries where most of the patients present with small renal masses (<4 cm), in developing countries, large masses or metastatic disease is the more common form of presentation [3]. Surgery is the mainstay of treatment in localized and few locally advanced renal cancers, whereas systemic therapy has been shown to extend survival in advanced and metastatic cases. With newer targeted therapy and immunotherapy agents being approved at a rapid pace, the paradigm of management of RCC is ever-evolving.

2 Incidence and Epidemiology in India and Worldwide

According to the GLOBOCAN 2020 data, kidney cancer accounts for 2.2% of malignancies around the world with more than 400,000 new cases per year and more than 175,000 deaths [4]. RCC is more prevalent in developed countries as compared to developing countries with younger age at the time of diagnosis (median 56 years) in the latter [3]. As per the SEER database, the incidence of renal cell cancer is steadily increasing across all age and racial groups [5].

The data regarding RCC in India is scarce. Ray and colleagues in their retrospective review found that the mean age of presentation of RCC in India was 52.7 years, which is a decade earlier than that in western countries [6–9]. The male-to-female ratio ranges from 1.5:1 to 2.5:1 across various Indian studies. Common risk factors for RCC include smoking, obesity and hypertension, with the strongest evidence for smoking [2, 10]. Ray et al. [6] assessed five risk factors for RCC in Indian patients and found nearly 73.3% of patients had one or more risk factors including a history of occupational exposure in a few patients (printing, rubber, dye industry).

3 Clinical Presentation

RCC may present in one of the following ways:

1. Asymptomatic—most of the small renal masses are detected incidentally on ultrasonography done for an unrelated abdominal complaint.
2. The traditionally described triad of symptoms (hematuria, flank mass and flank pain) is also called as the “too late triad” as it usually indicates advanced malignancy.
3. Symptoms suggestive of metastatic disease include bone pains, lymphadenopathy, dyspnea, cough, hemoptysis, jaundice, anorexia, weight-loss and fatigue.
4. Paraneoplastic syndromes are characteristically seen with RCCs in 20–30%. These include hypertension, erythrocytosis, hypercalcemia and jaundice.

In a large Indian series of RCC patients, most of the patients presented with symptomatic disease (80.7%) and incidental lesions were seen only in 9.3% [6].

4 Evaluation and Work-Up

4.1 Routine Laboratory Tests

These include complete blood count, renal and liver function tests, alkaline phosphatase and some other tests as needed, such as calcium, lactate dehydrogenase (LDH), electrolytes and urinalysis.

4.2 Radiology

1. *Abdominal USG*: This is usually the first investigation on which the mass has been detected. It is easily available and cheap [11]. The ultrasound can also distinguish between a solid and a cystic lesion. Further characterization of a cystic lesion would require axial imaging. A hyperechoic lesion, which suggests fat content, is almost diagnostic of an angiomyolipoma.
2. *Abdominal CT scan:* A contrast-enhanced CT scan of the abdomen and pelvis helps provide characterization of the renal mass and is the investigation of choice. A solid lesion that enhances more than 15 HU compared to the plain scan is almost diagnostic of an RCC. The Bosniak class of a cystic lesion can be determined which can help decide between observation vs. active intervention [12]. In a cystic lesion, thickened irregular walls or septa and solid enhancing areas are suggestive of malignancy. The CT scan will provide information to assign T, N and M staging to the renal mass. A note can be made of the anatomy of the renal vessels, presence of any tumor thrombus, loss of fat planes with any surrounding organs and presence of any hilar lymph nodes. All this information can aid in surgical planning. In a retrospective study of 100 RCCs patients by Johnson and colleagues, CT scan was found to have around 80–90% sensitivity and specificity for detection of renal vein invasion, metastatic lymphadenopathy and adjacent organ invasion except for detection of perinephric invasion where CT was found to have only 46% sensitivity [13].
3. *CT thorax:* This is performed to complete the metastatic evaluation and is superior to a chest x-ray [14]. Guidelines recommend performing a chest CT for all lesions which are larger than 4 cm in size.
4. *Magnetic resonance imaging (MRI):* A MRI scan may be performed if the patient has any contraindication to undergo a contrast-enhanced CT scan, like contrast allergy or reduced renal function. An MRI may also help in assessing for caval wall invasion in patients with IVC thrombus [15].
5. *Bone scan:* This is recommended only in patients who have bone pains or those with an elevated alkaline phosphatase level.
6. *Brain imaging:* An MRI brain should be performed in patients with neurological symptoms.
7. *Urine cytology:* This may be performed in patients with hematuria or those with a centrally located that is not intensely enhancing on the CT. Positive urine cytology will indicate a urothelial malignancy rather than an RCC. However, negative cytology does not rule it out.
8. *Renal biopsy:* Routine renal biopsy is not mandatory. The current role is in metastatic disease before initiation of systemic therapy or in the setting of a small renal mass, when active surveillance/ablative therapy is being contemplated instead of surgery. Other indications include a mass that is indeterminate for RCC on a CT scan, suspicion of lymphoma, metastasis from a different primary or an infective lesion [16].
9. *FDG PET scan:* Currently, PET alone has limited use for routine staging and follow-up for detecting relapse after nephrectomy in RCC [17].

4.3 Tumor Markers

The role of tumor markers in the diagnosis and management of RCC is currently very limited. In one particular study, high NSE (neuron-specific enolase) levels (examined by radioimmunoassay) were detected in 11 of 17 sera of patients with RCC. Positive rates for patients in stages II, III and IV were 100% (10/10) [18].

5 Pathology

RCCs were previously classified by cell type and growth pattern which has been changed to include morphology, growth pattern, cell of origin, histochemical and molecular findings to classify it into different subtypes. The current WHO classification system includes the following types of RCCs [19]:

1. Clear cell—70–80%.
2. Papillary—10–15%.
3. Chromophobe—3–15%.
4. Oncocytic—3–7%.
5. Renal medullary collecting duct.
6. Translocation associated [20].
7. Sarcomatoid variant; may be seen along with any of the above subtypes and carries a poor prognosis [21].

Classically, the Fuhrman grading system was for grading RCC. It is one of the most important histological prognostic factors but its prognostic value in nonclear cell RCC is unproven [22]. In a report by Tsui et al. the 5-year survival rates for tumors of histologic grade 1, 2 and 3 to 4 were 89%, 65% and 46%, respectively [23]. The widely used Fuhrman grading system has now been replaced by the International Society of Urological Pathology (ISUP) classification which relies solely on nucleolar prominence for grades 1–3, leading to less interobserver variation. Any presence of rhabdoid or sarcomatoid elements classifies a tumor as grade 4 in the ISUP system and is an indicator of poor prognosis.

6 Genetic Evaluation

Five to 8% of RCCs are hereditary. Hereditary RCC syndromes have distinct clinical and molecular phenotypes. Guideline recommendations for genetic counseling in RCC patients are as follows [24]:

1. Patients with any renal tumor (benign or malignant) and any one of the following:
    (a) Bilaterality or multifocality
    (b) Early age of onset (</= 45 years of age)
    (c) First- or second-degree relative with any renal tumor
    (d) One of the following associated tumors:
        - Pheochromocytoma/paraganglioma
        - Hemangioblastoma of retina, brain stem, cerebellum, spinal cord
        - Early-onset multiple uterine fibroids (<30 years of age)
2. Patient with nonclear renal cell carcinoma with unusual associated features (chromophobe, oncocytic or hybrid tumor)
3. Patients with or without RCC who report a family member (any) with known clinical or genetic diagnosis of any one of the following
    (a) Von Hippel–Lindau (VHL) syndrome
    (b) Birt–Hogg–Dube syndrome
    (c) Hereditary leiomyomatosis and renal cell cancer
    (d) Hereditary papillary renal cell cancer
        - *Staging* of renal cancer [25] can be found in the AJCC Cancer Staging Manual, Eighth Edition, Chapter 60, page no. 743–44, which can be accessed at https://emedicine.medscape.com/article/2006851-overview.

7 Anatomical Classification Systems

Various scoring systems, such as the Preoperative Aspects and Dimensions Used for an Anatomical (PADUA) score, the R.E.N.A.L. nephrometry score, the C-index, an Arterial-Based Complexity (ABC) Scoring System and Zonal NePhRO scoring system, have been described. THE RENAL nephrometry score is most commonly used and includes the following components:

- R: Radius. This scores the tumor size as its maximal diameter in mm
- E: Exophytic/endophytic component of the tumor
- N: Nearness of the tumor to the collecting system or renal sinus
- A: Anterior (a)/posterior (p) location of the tumor
- L: Location relative to the polar lines

Each individual component is assigned a score ranging from 1 to 3, for a total score ranging from 4 to 12. The suffix “x” is used when it is not possible to assign “a” or “p” to the tumor. An additional suffix “h” is used to indicate that the tumor abuts hilar structures.

Such scoring of renal masses allows the comparison of data across various reports and objective prediction of potential complications with nephron-sparing surgery and ablative techniques. It helps in choosing between partial vs. radical nephrectomy, choosing the approach to surgery and in patient counseling.

8 Principles of Management

The most important step in planning management is to accurately stage of the disease. In localized and certain locally advanced cases, surgical resection with curative intent is the mainstay of treatment—either in the form of a radical nephrectomy or NSS. The choice between the two is governed primarily by tumor factors (size and location) and patient factors (age, comorbid status, bilateral tumors) and partly by surgeon experience and skill. Following surgery, patients are kept on a strict follow-up schedule, the intensity of which depends on the pathological stage of the tumor. There is limited promising data available on the survival ben-

Table 1 Guidelines for management of localized or locally advanced RCC [26]

All clinically T1 tumors should undergo partial nephrectomy unless risk of margin positivity or any comorbidities precludes partial nephrectomy.
When partial nephrectomy not feasible, radical nephrectomy with preferred minimal invasive technique is treatment for organ confined RCC (stages T1T2N0NxM0).
For all radical nephrectomies, adrenalectomy and lymph node dissection are not recommended routinely.
In locally advanced RCC, open radical nephrectomy with goal of obtaining negative margins is still the standard of care.
Patients with small cortical tumors (≤ 3 cm) and age > 70 years, high surgical risk, solitary kidney, compromised renal function, hereditary RCC or multiple bilateral tumors ablative treatment can be considered.

efit of adjuvant therapy for high-risk tumors. The role of cytoreductive nephrectomy has declined following the publication of two major randomized controlled trials. However, it is still considered in the setting of a good-risk metastatic patient who can be offered metastasectomy at the same time. In unresectable locally advanced and intermediate/poor-risk metastatic disease, targeted or immunotherapy following a renal mass biopsy is the norm. (Table 1).

9 Surgical Management

9.1 Stage 1, 2 Disease (Tumor Limited to the Kidney)

9.1.1 Principles of Radical Nephrectomy (RN)

1. Early ligation of renal artery followed by the vein.
2. Removal of kidney along with the perinephric fat enclosed by the Gerota's fascia.
3. Ipsilateral adrenalectomy: Although this was classically described, the current practice is that the ipsilateral adrenal gland is removed only if there are any features of invasion on imaging or during intraop palpation of the gland.
4. Regional lymphadenectomy—Current evidence states that regional lymphadenectomy has only staging benefit and no therapeutic benefit. The only randomized controlled trial which evaluated the role of lymph node dissection in RCC did not find any survival benefit. However, the trial had some limitations one of which was that it included a substantial proportion of patients with <T3 disease and the incidence of lymph node metastasis in these patients is anyways very low [27]. The traditionally recognized features which should prompt one to perform a regional lymph nodal clearance in RCCs include tumor size >10 cm, T3–T4 tumors, grade 3–4 and evidence of tumor necrosis on imaging or on biopsy [28, 29].

Radical nephrectomy may be performed by one of the following approaches. None of them have any oncological benefit over the other. Choice of approach is again dictated by tumor factors, patient factors (age, comorbid status, BMI, affordability) and the surgeon's own experience and comfort with a particular approach:

1. Open: May be transperitoneal or retroperitoneal. The choice of incision depends on the size and location of the tumor and the comfort of the surgeon.
2. Laparoscopic: Transperitoneal, retro-peritoneal or hand assisted.
3. Robotic: Transperitoneal and extraperitoneal.

9.1.2 Nephron-Sparing Surgery

The indications for NSS are as follows:

Absolute: An anatomically or functionally solitary kidney where radical nephrectomy would render the patient anephric.

Relative:

1. If the contralateral kidney is affected by a condition which may compromise its function in the future such as diabetic nephropathy, calculus disease, hypertension.
2. Hereditary RCC—Increased risk of developing a contralateral renal tumor.
3. Elective—It is the treatment of choice in cT1a lesions and may also be offered in select cT1b and T2a tumors, depending on the surgeon's experience.

Various centers have reported excellent cancer-specific survival following NSS and as such, NSS is oncologically noninferior to radical nephrectomy [30–32]. A single-cell-negative margin has been shown to be sufficient, and this allows for enucleation of tumors in addition to other techniques like resection and enucleoresection [33]. Minimally invasive partial nephrectomy, either laparoscopic or robot-assisted, has also been described with comparable results and much faster patient recovery.

9.1.3 Ablative Techniques

Ablative procedures may be considered in the following settings:

- Elderly patients with significant comorbidities who have been deemed as having a high risk for a surgical procedure.
- Small incidentally detected tumors (only cT1a).
- Patients with bilateral tumors or tumor in a solitary kidney.

Ablative techniques include radiofrequency ablation (RFA), cryotherapy, microwave and high-intensity focused ultrasonic ablation (HIFU). A recent population-based study compared survival after surgery vs. nonsurgical management for small renal masses and noted that the recurrence-free survival was lower with these ablative techniques [34].

9.2 RCC with Tumor Thrombus (Extending to Renal Vein or Inferior Vena Cava [4–10%])

Tumor thrombi are classified as follows based on the cranial limit of the thrombus:

0: Thrombus within the renal vein only.

I: Thrombus extends into the IVC but for <2 cm from the renal vein ostium.

II: Thrombus extends up to lower border of liver (infrahepatic).

III: Thrombus extends into the intrahepatic portion of the IVC but below the diaphragm.

IV: Thrombus extends above the diaphragm.

Level III/IV thrombi may be associated with advanced locoregional disease and have poorer prognosis. Surgery remains the mainstay of treatment for RCCs with tumor thrombus and excellent 5-year survival of 40–70% has been reported with complete excision [35]. There have been reported attempts at shrinking the tumor thrombus with the use of neoadjuvant targeted therapy/immunotherapy. However, these are small reports and have shown a very modest response rate. Neoadjuvant therapy may be tried in case the tumor along with the thrombus is deemed unresectable on imaging.

9.3 Surveillance Following Surgery for RCC

There are no evidence-based surveillance guidelines. Various scoring systems are available which help to estimate the risk of recurrence in patients who have treated with a curative intent and this helps decide the intensity of surveillance. One of the commonly employed follow-up surveillance schemes is presented in Table 2 [36].

10 Medical Management

10.1 Adjuvant Treatment for Localized RCC

Various trials have evaluated the role of targeted therapy agents in the adjuvant setting. One of these studies (the S-TRAC trial) showed a disease-free survival benefit (median 6.8 years with sunitinib vs. 5.8 years in the observation arm) and on the basis of this result, sunitinib may be offered to patients who are at a high risk of relapse (pT3/4 or pN+ or those with grade 3/4) [37]. However, sunitinib is associated with significant toxicity and thus is not routinely used in the adjuvant setting. Moreover, the trial did not show any overall survival benefit. Various other trials evaluated other agents in the adjuvant setting like pazopanib, sorafenib and axitinib but none of them were able to demonstrate any survival benefit [38]. Recently, the KEYNOTE-564 trial published its results where 1 year of adjuvant pembrolizumab (17 three-weekly doses of 200 mg iv pembrolizumab) showed a disease-free survival benefit of 9% at 2 years (77% vs. 68%) and is now FDA approved for this indication. The high cost of this therapy is a major deterrent for its use.

11 Radiation Therapy

RCC has traditionally been considered to be an inherently radio-resistant tumor. However, there are recent reports of using Stereotactic Body Ablative Radiotherapy (SBRT) for small renal masses, with encouraging results. However, the use of radiation therapy for renal masses remains investigational at present and is not recommended for routine clinical practice. Another application of radiation therapy in RCC is in the setting of metastatic disease where it may be used in the ablation of small/few lung or bone metastasis in an attempt to achieve metastasectomy good-risk patients and also for palliation of painful bone metastasis and brain lesions.

14 Management of Metastatic Disease

The first step in the management of metastatic RCC is to risk stratify patients as the entire spectrum of metastatic RCC is very heterogeneous. Various risk stratification models have been developed by combining independent prognostic factors. The first such prognostic model was developed by the Memorial Sloan Kettering Cancer Center (MSKCC). It was based on a cohort of patients who were treated with interferons [40]. Eventually, interferons were replaced by tyrosine kinase inhibitors. Hence, in the new era of VEGF-targeted therapies, a new risk stratification model was developed and is known as the International Metastatic RCC Database Consortium (IMDC) model [41]. This model retained four of the five prognostic factors previously identified by MSKCC. It excluded LDH and added two more adverse prognostic factors, namely, absolute neutrophil count greater than the upper limit of normal (ULN) and platelets greater than the ULN. In the IMDC model, patients with none, 1–2 and 3 or more risk factors were classified as favorable, intermediate- and poor-risk patients respectively, and their median survival ranged from 43 months, for favorable risk to 22 months for intermediate-risk and a dismal 8 months for poor risk.

Cytoreductive nephrectomy (CN) before systemic therapy had been the traditional standard of care in patients with a resectable primary tumor and this practice was supported by large studies. A combined analysis of the SWOG and EORTC randomized trials showed that patients who underwent CN also received IFN-α had a median survival of 13.6 months compared to 7.8 months in patients who received IFN-α alone [42]. However, all these prior studies were performed in patients who had been treated with IFN-α; and the role of CN in the era of targeted therapy, which is more efficient than IFNs, was unclear [43]. The recently published CARMENA trial randomly assigned 450 patients in a 1:1 ratio to either receive sunitinib alone (intervention arm) or undergo a CN followed by sunitinib (standard arm). It was found that sunitinib alone was noninferior to CN followed by sunitinib. Not all patients who underwent CN were able to receive sunitinib due to postoperative morbidity. Thus, the trial concluded that metastatic RCC patients should be started on targeted therapy and a CN may be considered later in responders. This strategy would ensure that all patients receive systemic therapy which is pivotal in the management of metastatic cancer. However, a major limitation of this trial was that it included only intermediate- and poor-risk patients. Thus, the ideal treatment strategy for good-risk patients remains to be defined. Guidelines recommend CN for good-risk patients especially if the metastatic sites can also be treated either by resection or SBRT, which can render the patient as "no evidence of disease (NED)." Further evidence suggests that even intermediate-risk patients with only one adverse risk factor may benefit from CN [44].

15 Systemic Therapy for Metastatic RCC

15.1 Targeted Therapy

The discovery of VHL mutations and the activation of VEGF, PDGF and other genes involved in angiogenesis, cell growth and survival led to the development of several targeted therapies that have improved the clinical outcomes of patients with metastatic RCC.

For a long time, *sunitinib* (against the VEGF receptors, PDGF receptors and other kinases) had been the first-line therapy for the treatment of patients with upfront metastatic RCC based on the results of a phase III trial by Motzer et al. [45]. Sunitinib 50 mg/day (4 weeks on and 2 weeks off) produced a significantly higher objective response rate than IFN-α (31% vs. 6%). Later, updated results of this trial showed a trend toward better OS with sunitinib over IFN-α (26.4 months vs. 21.81 months, $p = 0.051$). To manage the toxicity associated with sunitinib, alternate regimens have also been tried which have used 2 weeks on and 1 week off.

Pazopanib (multitargeted, small-molecule TKI) was evaluated in a randomized phase III trial (2:1 for pazopanib or placebo) and it was shown to significantly prolong the progression-free survival (9.2 months vs. 4.2 months) [46]. A large noninferiority trial compared sunitinib and pazopanib (COMPARZ) showed that although the two drugs have comparable efficacy (median PFS was 9.5 months for sunitinib vs. 8.4 months for pazopanib), pazopanib had a better side-effect profile and was associated with lesser incidence of fatigue, hand-foot syndrome and thrombocytopenia [47]. In an another patient-preference study, pazopanib was preferred by patients in view of better tolerability.

Bevacizumab, an angiogenesis inhibitor and monoclonal antibody against VEGF, in addition to IFN-α was compared with placebo plus IFN-α. A significantly longer PFS (10.2 vs. 5.4 months) was seen with the combination with no significant increase in side-effects [48]. Bevacizumab is rarely used in today's practice due to the availability of much more efficacious agents.

Almost all trials evaluating sunitinib and pazopanib included only MSKCC good and intermediate-risk patients, and thus, the results of those trials could not be extrapolated to patients belonging to the poor-risk category. In a retrospective study, sunitinib resulted in median OS of 8.16 months in poor-risk patients [49].

Another TKI, *cabozantinib* was compared with Sunitinib in a phase 2 randomized trial (CABOSUN) which included 157 first-line intermediate- and poor-risk metastatic RCC patients. Cabozantinib showed a significantly improved PFS (median 8.2 vs. 5.6 months) and was associated with a higher objective response rate of 46% vs. 18% for sunitinib. However, this did not translate to any OS benefit [50].

Axitinib, an oral selective inhibitor of VEGF was compared in the AXIS trial to sorafenib in patients who had failed on sunitinib. Axitinib therapy resulted in a longer PFS (median 4.8 vs. 3.4 months); however, this did not translate into OS benefit [51]. Axitinib was also compared to sorafenib in a phase 3 RCT as first-line therapy for metastatic RCC; however, no significant difference in the PFS was seen [52].

Lenvatinib is an oral inhibitor of VEGF and PDGF and also has inhibitory activity against fibroblast growth factor receptors (FGFRs). It has been evaluated in combination with everolimus and is discussed below under the section of combination therapies [53].

15.2 Immune Checkpoint Inhibitors-Based Combination Therapies

Immune checkpoint inhibitors-based combination therapy has superseded single agent targeted therapy as the first-line therapy for metastatic RCC. Various combinations have been evaluated in large phase 3 RCTs and are summarized below.

1. CheckMate 214 trial (NCT 02231749) *Nivolumab (programmed death 1 (PD-1) inhibitor antibody) plus Ipilimumab (anti-cytotoxic T-lymphocyte associated antigen 4 antibody)* vs. *sunitinib* [54].

   This trial included only IMDC intermediate- and poor-risk patients and the combination therapy showed an OS benefit with an HR of 0.63. These results led to a paradigm shift in the management of metastatic RCC. A recent with 60-month follow-up showed a 5-year OS probability of 43% for the combination vs. 31% for sunitinib [55].

2. KEYNOTE-426 trial (NCT02853331) *Combination of axitinib plus pembrolizumab (PD-1 inhibitor)* vs. *sunitinib* [56].

   Median OS for the combination was significantly longer at 45.7 months compared to 40.1 months for sunitinib. Subgroup analysis revealed that the OS was similar in the favorable subgroup while an OS benefit was seen with the intermediate- and poor-risk patients. The PFS benefit (HR 0.68; 95% CI: 0.58–0.80) was seen across all risk groups. Treatment efficacy was seen regardless of PD-L1 status.
3. CheckMate 9ER trial (NCT03141177) *Combination of nivolumab plus cabozantinib* vs. *sunitinib* [57].

   The combination significantly prolonged the PFS compared to sunitinib (16.6 months vs. 8.3 months). A significant benefit was also seen with OS (HR 0.60; 95% CI: 0.40–0.89) at a median follow-up of 18 months. Efficacy of this combination was seen across all risk groups and irrespective of PD-L1 status. Severe side-effects (grade 3 and more) were seen in 61% receiving the combination vs. 51% receiving sunitinib alone.
4. CLEAR trial (NCT02811861) *Lenvatinib + Everolimus or Lenvatinib + Pembrolizumab* vs. *Sunitinib Alone* [58].

   The Lenvatinib plus pembrolizumab combinations showed a significantly longer PFS compared to sunitinib alone (median 23.9 months vs. 9.2 months). An OS benefit was also seen with this combination (HR 0.66; 95% CI: 0.49–0.88). The lenvatinib plus everolimus combination did demonstrate a longer PFS (median 14 months) compared to sunitinib alone; however, no OS benefit was seen with this combination.
5. JAVELIN trial (NCT02684006) *Avelumab plus axitinib* vs. *sunitinib* [59]

   This combination did show PFS benefit compared to sunitinib in patients who were PD-L1 positive. However, the OS data is yet to mature and this combination is not recommended by guidelines yet.

It is important to note that all the above combination therapies have been evaluated against single-agent sunitinib. There is no prospective data comparing any of the combinations and as such, no recommendation can be made for one particular combination over the others. The decision of choosing a particular combination for a particular patient depends on the patient's tolerability with regards to any specific side-effects of any agent, affordability and availability issues and finally, on the clinician's acumen. This particular field in the management of metastatic RCC is ever evolving and newer agents and their combinations are getting approval based on robust phase 3 RCT data. As of May 2022, the agents recommended by guidelines for first-line management of metastatic clear cell RCC are summarized in Table 4. For subsequent therapy following progression, out of TKI and immunotherapy, whichever agent was not used in first-line therapy, may be tried. For third-line therapy, only cabozantinib has data from a phase 3 RCT and may be used preferentially if not used earlier.

Table 4 Guideline recommendations for first-line therapy in metastatic clear cell RCC

Risk category	Preferred regimens	Other regimens
Favorable	Pembrolizumab + Axitinib Cabozantinib + Nivolumab Pembrolizumab + Lenvatinib	Cabozantinib Pazopanib Sunitinib
Intermediate/poor	Pembrolizumab + Axitinib Cabozantinib + Nivolumab Pembrolizumab + Lenvatinib Nivolumab + Ipilimumab	Cabozantinib Pazopanib Sunitinib

15.3 Nonclear Cell metastatic RCCs

There is no phase 3 RCT data available to provide any recommendations for nonclear cell metastatic RCCs. The ASPEN study was a phase 2 trial that evaluated everolimus vs. sunitinib in 108 such patients. Those treated with sunitinib had a significantly better PFS compared to everolimus (8.3 months vs. 5.6 months), and thus, sunitinib may be used as the preferred agent in these patients [60].

TNM	Tumor-node-metastasis

1 Introduction

Adrenal cancer, also known as carcinoma, is a rare but aggressive malignancy that affects people of all ages. In many cases, the diagnosis occurs in the metastatic stage. The investigations are primarily used to stage the disease and determine whether the adrenal cancer is secreting hormones or this is a non-secretary tumor. Treatment options can be complex, and multimodality treatment is beneficial. Optimal care is offered with the involvement of surgical oncologists, medical oncologists, endocrinologists, and radiation oncologists.

2 Incidence and Epidemiology: Global and India

Adrenal cortical carcinoma (ACC) is uncommon cancer with an aggressive course with poor outcomes. The reported annual incidence is about 1–2 cases per million [1]. In the United States, as per the Surveillance, Epidemiology, and End Results (SEER) database, the incidence is 0.7 cases per million per year and 0.2% of all cancer deaths [2, 3]. ACC has two peaks in early childhood and second in the fourth and fifth decades of life, although this can affect any age with a slightly increased female preponderance [3].

3 Genetic Predispostion

3.1 Inherited/Germline

ACC in childhood is usually associated with various genetic disorders affecting TP 53 mutation and alternation in the insulin-like growth factor 2 (IGF-2). This is commonly seen in patients having Li–Fraumeni syndrome (50–80% of pediatric ACC), Beckwith–Wiedemann syndrome, multiple endocrine neoplasia Type 1, Carney complex, and congenital adrenal hyperplasia. Lynch syndrome also has an association with ACC as reported in a series of 114 patients diagnosed with ACC, 3.2% have underlying Lynch syndrome. Patients of ACC with Lynch syndrome may have MSH2, MLH1, and MSH6 germline mutations [4].

3.2 Acquired

In most adult-onset ACC, either there is TP53 inactivating mutation or activating mutations of the proto-oncogene b-catenin (CTNNB1) or [5, 6] ZNRF3 (zinc and ring finger protein 3) gene mutation, which is involved in the Wnt signaling pathway [6]. Chromosomal gains, detected by comparative genetic hybridization at 5, 7, 12, 16, 19, and defeats

at 13 and 22, have also been seen along with the hypermethylation of specific gene promoters in H19, PLAGL1, G0S2, and NDRG2. Recently, micro RNA specifically, upregulation of miR-483 and an ACC miR-195 and miR-335 downregulation has also been seen in a few cases of ACC [7].

With the evolving data of TCGA (The Cancer Genome Atlas), a few new genes such as PRKAR1A, RPL22, and TERF2 were also associated with ACC. Telomere maintenance, specially TERF2, plays a vital role in developing ACC [8]. Although IGF-2 is overexpressed in the majority of the ACC; still, the IGF-1 receptor-mediated downstream pathway which activates the protein kinase B Akt/mechanistic target of the rapamycin (mTOR) does not have a role in the pathogenesis of ACC. This hypothesis has also been further proved as IGF-1R/mTOR signaling pathway inhibitors have not shown any benefit in ACC patients. Other pathways, such as hepatocyte growth factor (HGF) and cMET, have been activated in ACC. The different path that has been activated is HGF/cMET, which is associated with its downstream way, leading to increased cell proliferation, apoptosis inhibition, angiogenesis, resistance to chemotherapy, and finally, cell survival [9].

4 Clinical Presentation: Global and India

Approximately half of ACC patients present with signs and symptoms of increased hormone production by the tumor, including clinical Cushing's syndrome and female virilization [10]. Rest one-third present with local symptoms due to tumor growth and involvement of adjacent organs; this can include abdominal fullness, early satiety, and dull aching pain radiating to the back (9, 10). Rest 30% of ACCs are diagnosed when imaging is done for unrelated issues; these are the incidentally detected ACC and mostly non-secretary types. Although estrogen hypersecretion is rare (1–3%), this can lead to gynecomastia and testicular atrophy. This is pathognomonic for ACC [11]. Childhood ACCs are more hormone secreting as compared to adult patients. In children, the adrenal cortex's persistent fetal zone produces dehydroepiandrosterone sulfate (DHEA-S), leading to virilization [12].

5 Evaluation and Work-Up

5.1 Biochemical

Most ACC secrete hormones; hence, comprehensive endocrine assessment is an integral component of any suspected adrenal mass lesion in the preoperative workup. Biochemical workup helps establish or exclude the diagnosis of excess hormone production, the adrenocortical origin of a tumor, future follow-up, and surveillance, and assessing the requirement of postsurgical hydrocortisone therapy. European Network for the Study of Adrenal Tumors (ENSAT) has proposed the panel of hormones in a suspected case of ACC of excess glucocorticoids (basal cortisol and 1 mg dexamethasone suppression test), sex steroids and their precursor (DHEA, 17- hydroxyprogesterone, androstenedione, testosterone in women, 17-beta-estradiol in men, 11-deoxycortisol minerlocorticoids excess (aldosterone/renin ratio, serum potassium), and also plasma-free metanephrines or urinary fractionated metanephrines to rule out pheochromocytoma [13].

5.2 Radiology

CT scan, USG abdomen, MRI scan, and PET CT are used to evaluate adrenal lesions with the pros and cons of each modality.

Imaging is done for staging and tumor relationship with the surrounding organs and vessels to assess the possibility of surgery and determine the therapy response in case of metastatic disease during follow-up. Three-dimensional reconstruction of CT or MRI images helps to understand better the morphology and relationship of ACCs with the surrounding structure and subsequent decision for open versus laparoscopic removal of the tumor [14].

Computed tomography: CT scan of the abdomen and pelvis is the most commonly used first choice. Typical features of ACC which differentiate ACC from adrenal adenoma include the large size of the tumor, irregular borders, areas of necrosis, hemorrhage, and calcification leading to heterogeneous appearance and, in some cases, invasion into the surrounding structure [6, 15, 16]. The size of the adrenal lesion directly relates to the potential malignant nature. If the mass size is greater than 4 cm, the sensitivity and specificity are 97% and 52%. If the size is greater than 6 cm, the sensitivity is 91%; specificity is 80% for the lesion to be adrenocortical carcinoma rather than adenoma [17]. In an unenhanced CT, the calculation of tissue density, which denotes the intracellular lipid content by measuring Hounsfield units (HU), is also helpful in distinguishing adenoma from ACC [11]. Usually, HU threshold of $\leqslant 10$ indicates a benign lesion, and a HU of >10 is suggested to indicate malignancy. But the difference between benign and malignant adrenocortical tumors based on imaging is not always straightforward. 13 HU is the cutoff for differentiating adenoma from carcinoma [18]. Another way is to get the contrast-enhanced CT scan, washout time [6, 11]. Although this approach has limitations, the adenomas have complete washout >50% compared to ACC, which retains the contrast longer. The MRI sensitivity is the same as CT differentiating adrenal adenomas from carcinomas. The sensitivity and specificity ranged from 84% to 100% and 92% to 100%. MRI feature which is specific to ACC includes isointense to hypointense signals on T1-weighted images and a heterogeneous signal drop on chemical shift [19, 20].

FDG-PET CT is a useful investigation for indeterminate cases on CECT scans. This is also useful to exclude distance metastasis. PET/CT may be used instead of CT in patients with impaired renal function. A combination of PET with CECT (FDG-CECT) can be considered a baseline assessment in an operable case of ACC. This can also help assess the response of palliative chemotherapy in metastatic cases [21, 22].

Newer tracers are also being tried in ACC cases. C-etomidate PET and (123) I-iodometomidate SPECT imaging are one of them. These tracers help distinguish between adrenocortical and nonadrenocortical lesions also metastases from adrenocortical carcinoma [23].

5.3 Biopsy

If a biopsy is clinically indicated, it is advisable to rule out pheochromocytoma biochemically to rule out the possibility of a fatal catecholamine surge during the procedure [24, 25]. Few studies show that biopsy increases the risk of morbidity and mortality [26, 27]. The decision on the need for adjuvant therapy should not be based on previous biopsy status and has not shown any relation to survival [28].

5.4 Pathology

Most ACCs are heterogeneous tumors with the invasion of the tumor capsule and associated nearby vital structures. The color of the resected mass varies from brown to yellow as per the lipid content inthe tumor tissues [6]. Histopathologically, it is tough to differentiate between adrenocortical tumors from carcinomas [29]. Weiss scoring system is one of the ways to determine the ACC from adrenal adenoma by looking into microscopic features on histopathology. This Weiss scoring system combines the nine morphological features, including nuclear atypia, mitotic index, atypical mitoses, diffuse architecture, confluent necrosis, clear cells, sinusoidal, venous, capsular (Table 1). Weiss score of 3 or more indicates an ACC, and 0 to 2 suggests an adenoma [30, 31].

The Ki-67 is a marker of proliferation (Ki-67 LI) and has shown a good correlation with survival. KI-67 value greater than 10% has shorter overall survival (OS) and more risks of local recurrences [32]. This also correlates with the Weiss criteria in predicting the aggressiveness of the tumors and is commonly reported by pathologists [33].

Table 1 Weiss Scoring System

Histological criteria	Score 0	Score 1
Nuclear grade[a]	1 and 2	3 and 4
Mitoses	≤ 5 for 50 fields × 400	≤ 6 for 50 areas × 400
Atypical mitoses	No	Yes
Clear cells	>25%	≤ 25%
Diffuse architecture	≤ 33% surface	> 33%
Confluent necrosis	No	Yes
Venous invasion	No	Yes
Sinusoidal invasion	No	Yes
Capsular infiltration	No	Yes

[a] Grade 1: (round nuclei, homogenous, small size, no nucleoli); Grade 2: (nuclei slightly irregular, more voluminous, conspicuous nucleoli at × 400); Grade 3: (unstable nuclei, voluminous nucleoli at × 100); Grade 4: (the same as Grade 3 with monstrous cells and very irregular nuclei)

Table 2 TNM classification system, proposed by ENSAT. T1, <5 cm; T2, >5 cm; T3

Stage	Characteristics		
I		T1, N0, M0	
II		T2, N0, M0	
III	T1-T2, N1, M0 T3-T4, N0-N1, M0		
IV	Any T, any N, M1		

6 ACC Staging

The most common staging system that is used for staging is ENSAT (European Network for the Study of Adrenal Tumors), which consists of the tumor, lymph node, and metastasis classification system that takes account of local extension of the primary tumor, lymph node involvement, and the presence of distant metastasis (Table 2). The Weiss system and TNM staging have an excellent concordance in predicting the prognosis of ACCs. TNM Stages III and IV patients usually have a high Weiss score [34]. The main difference between the ENSAT staging system and AJCC tumor-node-metastasis (TNM) classification is in stage III disease which in ENSAT includes patients with positive lymph nodes (N1), infiltration of surrounding tissues (T3 and T4), and venous tumor thrombus.

7 Management Principles

Management entails proper diagnosis and staging. Appropriate and sufficient investigations are required. It should ideally be a multidisciplinary team (MDT) effort. If the stage is possible, surgery to altogether remove the disease would be the first option. Adjuvant therapies, salvage therapies, and the treatment of metastatic disease are all difficult to administer and may not produce the desired results. They are used sparingly, as prescribed by MDT.

8 Surgical Management

Surgery is the only curative treatment in the case of operable ACCs, followed by adjuvant therapy in selected patients. Surgery can be done either by open adrenalectomy (OA) or minimally invasive surgery (Fig. 3). Staging the disease is essential before planning the surgery. This helps get information on the invasion of adjacent organs and distant metastases present in one-third of patients, mainly in the lung and liver [10]. A retrospective study of 201 patients underwent adrenalectomy for primary ACC (47 minimally invasive and 154 open surgery). All the postoperative histopathological parameters, post-op morbidity, and complications are similar; hence, in an experienced hand and adequately selected patient, minimally invasive surgery is a safe alternative to open surgery [35]. A recent metanalysis of nine retrospective case–control studies concluded no difference in overall recurrence rate or time to recurrence, or cancer-specific mortality between open and laparoscopic adrenalectomy. Laparoscopic adrenalectomy can result in a shorter hospital stay and faster recovery. Rarely laparoscopic approach was associated with a higher risk of peritoneal carcinomatosis because of the possible tumor capsule rupture during manipulation [36]. Complete surgical resection is the most crucial factor in the management of ACCs, and approximately two-thirds to three-quarters of ACCs have lymph node involvement [37, 38]. The role of routine lymphadenectomy during ACC surgical resection is still debatable, and its therapeutic role has not been proven, well-established predictor of poor long-term outcomes, however. In a multi-institutional study of 120 ACC patients undergoing complete resection, peritumoral lymph node dissection (performed in 27% of ACC patients) was independently associated with improved OS. It was also associated with large tumors macroscopically involved lymph nodes or invasion of adjacent organs [39]. In another review of the German ACC registry, lymphadenectomy was associated with improved disease-specific survival [40]. In contrast, in an extensive population study, data from 18 registries having 1525patients with ACC has not shown any survival benefit of lymphadenectomy. Lymphadenectomy is generally recommended in patients with locally advanced tumors (T3 and T4), which have more probability of lymph nodal involvement [41]. Debulking surgery of primary lesion in a metastatic condition has shown good palliative benefits. The removal of cancer also reduces the source of excess hormone in a secretory tumor without any significant improvement in median survival [11]. In patients with limited lung and liver metastasis at diagnosis, removal of primary and metastasectomy to achieve R0 resection has shown better long-term survival [42, 43]. Patients with ACC, who underwent curative surgery, have a high probability of recurrence, especially in higher stage patients, and can be seen in 40–65% of cases within 2 years. The average median time to recurrence is 19 months [44]. Patients presenting with limited recurrence and are amenable to curative-intent resection may be offered surgery as this approach is associated with improved long-term survival. Factors related to enhanced survival include solitary tumor, disease-free interval > 12 months, and locoregional or pulmonary recurrence [45].

9 Medical Management

9.1 Mitotane

This can be used as adjuvant or palliative therapy for the symptomatic benefit or combined with chemotherapy in the palliative setting [5]. There is no uniform consensus regarding the use of mitotane as adjuvant therapy. As per the ESMO guidelines, mitotane can be considered in Stage III, Ki-67 > 10%, microscopic margin positive, or gross positive resection [46].

With mitotane level monitoring, adjuvant mitotane is preferably started within 3 months of surgery. The intended level is to keep the mitotane between 14 and 20 mg/L. In a retrospective analysis, blood mitotane concentrations of more than 14 mg/L were associated with more prolonged recurrence-free survival [47]. Significant side effects include nausea, vomiting, raised liver enzymes, low WBC count, confusion, and other neuropsychiatric symptoms [48].

9.2 Chemotherapy

FIRM-ACT trial was a randomized phase 3 study of the combination of etoposide, doxorubicin, and cisplatin (M-EDP) with mitotane versus a combination of streptozocin with mitotane. Patients who received M-EDP had a higher response rate than those who received streptozocin plus mitotane (23.2% vs. 9.2%) and longer median progression-free survival (5.0 months vs. 2.1 months); however, there was no significant difference in overall survival (14.8 months and 12.0 months, respectively; hazard ratio, 0.79; 95% CI, 0.61 to 1.02; $P = 0.07$) [49].

For patients who had progressive disease on first-line treatment with M-EDP, chemotherapy with a combination of gemcitabine and capecitabine as a second-line therapy is an option. This combination regimen resulted in a nonprogressive disease in 46.3% of patients at the end of 4 months of treatment [50, 51].

9.3 Targeted Therapy

Various newer targeted therapies and monoclonal antibodies, such as bevacizumab, sorafenib, gefitinib, erlotinib, sunitinib, and axitinib, have not shown any encouraging results. Other newer targeted agents against steroidogenic factor-1, mTOR, and Wnt signaling pathways are under the process of development. Of these inhibitors, particular interest is on target acting against acetyl-CoA cholesterol acetyltransferase 1, an enzyme involved in intracellular cholesterol transport, is underway. It has shown promising activity in preclinical studies. Many phase I and II studies are ongoing for these novel agents and may be helpful for clinical applications in the future [52].

9.4 Radiation Therapy in the Management of ACC

The role of adjuvant radiotherapy (AR) in ACC is still evolving due to the lack of any randomized phase III studies. Various retrospective case series have shown benefits in local recurrence-free survival without affecting the disease free or overall survival. In a retrospective study from the German ACC cohort, the local recurrence 5 years after surgery was 79% in no adjuvant RT versus 12% in the adjuvant RT cohort without affecting the disease-free and overall survival [53, 54]. Another study by Habara et al. found no difference in the 5-year local recurrence-free rate between AR surgery and surgery alone (5 years local recurrence-free rate 53% (32–87%) in the RT group and 67% (52–86%) in the non-RT group ($P = 0.53$) [55]. Sabol et al. compared the non-radiotherapy treatment regimens with adjuvant RT. The use of adjuvant RT was associated with a 4.7-fold decrease in the risk of local recurrence [56]. Although the data for the benefit of adjuvant RT is not robust, with the available literature, adjuvant radiotherapy is strongly recommended in patients who have an incomplete resection, those with positive margin resection, and all those patients at high risk of local recurrence [11].

Stereotactic body radiotherapy (SBRT), which aims at delivering high-dose radiation, is an option for minor, localized recurrence and also for palliative therapy in a subset of patients with advanced adrenocortical carcinoma [57].

10 Algorithms for Stage-Wise Management (Fig. 4)

11 Prognosis by Stage with Current Treatment (Table 3)

Table 3 Stage-wise prognosis

Stage	5-year survival
I	33–66%
II	20–58%
III	18–24%
IV	<5%

12 Palliative Measures

In patients presenting with metastatic disease, no curative option is available. Treatment aims for the symptomatic benefit primarily associated with the excess catecholamine secretion and local and metastatic disease spread. Treatment options include locoregional therapies, systemic chemotherapy, and radiopharmaceutical agents [58]. The treatment plan should be preferably discussed with a multidisciplinary team. Some patients benefit from local embolization and radiofrequency ablation, even in metastatic settings.

Radionuclide therapy with 131I MIBG is effective in selected cases. There are few studies on the efficacy of 131I-MIBG treatment in the palliative setting. Responses rates were ranged from 22% to 47%, with few long-term control lasting for 4 years. More objective responses were seen in patients having soft tissue metastases [59, 60].

How We Do It at TMC

- Detailed history, examination, vitals.
- Specific blood tests—for an adrenal mass glucocorticoids, mineralocorticoids, sex.
- Steroids and catecholamine levels.
- Imaging as required—CT scan/MRI/FDG PET CT scan.
- Endocrinology reference/evaluation.
- MDT discussion.
- Treatment as decided in MDT tumor board.
- Post therapy MDT discussion and follow-up/adjuvant or additional therapy.

Urinary Bladder Cancer

Gagan Prakash, Amit M. Gupta, Sahil Sood,
and Vedang Murthy

Abbreviations

CIS	Carcinoma in situ
CMV	Cisplatin, methotrexate, vinblastine
DCE	Dynamic contrast enhanced
DNA	Deoxyribonucleic acid
DSS	Disease-specific survival
FDG	18F-fluorodeoxyglucose
GC	Gemcitabine and cisplatin
IGRT	Image guided radiotherapy
IMRT	Intensity-modulated radiation therapy
MIBC	Muscle-invasive bladder cancer
MMC	Mitomycin C
M-VAC	Methotrexate, vinblastine, doxorubicin and cisplatin
NBI	Narrow-band imaging
NMIBC	Non-muscular invasive bladder cancer
PTV	Planning target volumes
RNA	Ribonucleic acid
TNM	Tumour, node, metastasis
TURBT	Transurethral resection of bladder tumor

1 Introduction

Bladder cancer is the most common malignancy of the urinary system and the ninth most common malignancy worldwide [1]. Carcinoma of the bladder can present as a superficial disease or locally advanced muscle-invasive or metastatic disease. This heterogenous presentation warrants different management strategies and has different survival outcomes.

2 Incidence

As per GLOBOCAN 2018, the age-standardized incidence rate in US and India is 12 and 1.5 (per 100,000 population) respectively [2]. It is the fourth most common cancer in men and the eighth most common malignancy in women in the Western world [3]. In the United States, approximately 81,000 new cases and 17,000 deaths occur each year due to bladder cancer [4]. There has been an increase in the age-standardized incidence rate by 13·6% (95% CI - 1·0 to 22·0)) from 1990 to 2016 in India [5]. In males, the genitourinary system formed 17.48% of all the malignancies (urinary bladder [30.40%]) [6].

Bladder cancer is typically diagnosed in older individuals, with a median age at diagnosis of 69 years [7], and has a male preponderance (86.4% male vs. 13.6% female) [8].

3 Epidemiology

Cigarette smoke: the most important factor [9]. Heavy smokers (≥ 30 pack years) are more prone to advanced-stage disease or high-grade tumor [10]. Smoking cessation decreases the risk.

Chemicals: paint components, polycyclic aromatic hydrocarbons such as 2-naphthylamine, benzidine, and diesel exhausts, cyclophosphamide administration over the long term.

Chronic irritants: including catheters, recurrent urinary tract infections, Schistosoma haematobium, and irradiation (for squamous carcinoma).

Genetic abnormalities: 17p deletion, p53 expression, RB gene expression, 9q aberration.

Table 1 Clinical presentation [12–14]

Clinical presentation	Incidence of bladder cancer
Gross painless hematuria (80–90%)	10–20%
Microscopic hematuria	2–5%
Irritative voiding symptoms (dysuria, urgency, frequency) 20–30%	Indicates CIS
Pain: • Flank pain: associated with muscle-invasive disease or large non-invasive tumors at the ureteral orifice • Suprapubic pain: involvement of perivesical tissue or nerves/bladder outlet obstruction • Perineal pain: involvement of obturator fossa, perirectal fat, presacral nerves, or the urogenital diaphragm. • Right upper quadrant upper abdominal pain: presence of abdominal lymph node or liver metastases. • Bone pain: the presence of bone metastasis • Persistent headache or disordered cognitive function: presence of intracranial or leptomeningeal metastases	–

4 Clinical Presentation in India and Globally

At presentation, 1/third are muscle-invasive tumors, of which 5–10% are metastatic [11]. Painless hematuria is the most common presentation with irritative voiding symptoms present in only one-third of patients. (Table 1) [12–14].

Locally advanced tumors usually present with painful obstructive symptoms due to ureteric orifice involvement and sometimes with constitutional symptoms of renal failure due to bilateral ureteral obstruction. Failure to thrive, weight loss, fatigue, and anorexia are the usual mode of presentation in metastatic patients indicating poor prognosis.

Episodic hematuria presentation in middle-aged smokers or those with exposure to industrial carcinogens needs a word of caution and should be thoroughly investigated for bladder carcinoma. Urine cytology, cystoscopy, and imaging (CECT-IVU) are suggested.

5 Investigations

The important objectives of investigation in bladder cancer are diagnosing the presence or absence of muscle invasion and staging the patients appropriately for optimum care.

Urine Cytology:

In high-grade tumors or carcinoma in situ (CIS), the sensitivity of freshly voided urine cytology samples is high (~90%) even with unequivocal imaging findings indicating lesions anywhere in the urinary tract. Since the overall sensitivity of urine cytology examination is low (sensitivity: 40–60%, specificity: 90%), negative cytology does not exclude the presence of low-grade bladder tumor [15].

Table 2 Urinary biomarkers for diagnosing urothelial cancers of the bladder [16, 18, 19]

Target	Sensitivity (%)	Specificity (%)	False positives
Bladder tumor antigen (BTA)	50–90	90	Urinary tract infection, hematuria, calculi, BPH, prior intravesical treatment
Nuclear matrix protein (NMP 22)	42–100	70–91	Inflammation
NMP 52	97	94	–
Bladder cancer associated NMP 4 (BCLA −4)	89–96	95–100	–
BCLA-1	80	87	–
Survivin	64–100	93–100	–
Cytokeratin 8 and 18	35–79	68	–
CK 19	43–96	70	Urinary tract infection, calculi, post-BCG
Fibrin degradation products (FDP)	70	68–86	–
Hyaluronic acid, hyaluronidase	82–100	81–90	–
mRNA markers (IGFBP5, HOXA13, MDK, CDK1, CXCR2	74–95	45–81	–

6 Tumor Markers

Tumor markers are considered as a non-invasive diagnostic tool to supplement cystoscopy (pooled sensitivity of 50–80% and specificity of 70–90%) due to the low sensitivity of urine cytology examination [16, 17]. It correlates closely with the stage and grade of the tumor. Multiple urine-based tumor markers were developed based on differential expression of tumor-related proteins, deoxyribonucleic acid (DNA), ribonucleic acid (RNA), or cellular markers (Table 2) [16, 18, 19].

Potential applications of urinary biomarkers:

1. Presence of hematuria and irritative voiding symptoms, atypical findings on cytology or cystoscopy, as they are at high risk of tumor diagnosis.
2. Surveillance: Treated non-muscle invasive tumors to detect recurrences.
3. Evaluation of upper tract radiographic abnormalities and monitoring patients after treatment of ureteral or renal pelvic urothelial carcinoma.
4. Predicting outcomes for patients being treated with intravesical immunotherapy, but this awaits validation [20].

Limitations:

Unnecessary imaging and bladder biopsies are the drawbacks associated with its higher false positive rates.

Since the cost-effectiveness and incremental benefit of markers are unknown, additional clinical trials are necessary.

7 Endoscopy

The gold standard for diagnosis of bladder cancer. (Fig. 1).

1. The presence of a palpable mass on bimanual examination under anesthesia implies an extravesical disease or fixity to pelvic side walls, which helps in the local staging of tumors especially invasive tumors.
2. Cystoscopy helps in visualizing the size, stalk, and configuration of the cancer, which can be the predictive factor of muscle invasion [21]. Papillary tumor with narrow stalk indicates low-grade non-invasive malignancy, whereas sessile tumour with solid or nodular pattern is seen more frequently in high-grade malignancies. Carcinoma in situ are exceptions, as they are high-grade but non-invasive and appear as flat velvety lesions in patches, sometimes can involve large areas of the urothelial lining.

7.1 Principles of Cystoscopy + TURBT

1. Any visible tumor or suspicious lesion seen at the initial (diagnostic) cystoscopy should be either biopsied or transurethrally resected down to the muscle. Superficial and deep tissue should always be sent separately to determine the histology and depth of invasion by oncopathologist. (Table 3) [15].
2. Positive urine cytology with negative cystoscopy examination findings require a biopsy of apparently normal-appearing urothelium, prostatic urethra, and selective catheterization of the ureters/renal pelvis to retrieve urine specimens for cytology from the upper tract.

There is no role for random biopsies in a patient with a solitary papillary lesion as the incidence of CIS is less than 2% and the risk of accidental tumor cell implantation with no additional information.

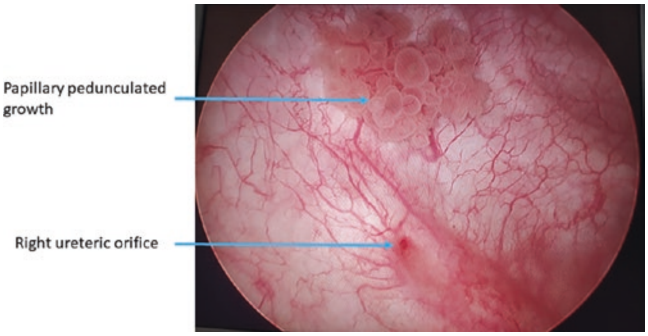

Fig. 1 Cystoscopy image showing papillary pedunculated growth above right ureteric orifice suggestive of urothelial bladder cancer

7.2 Enhanced Cystoscopy

Fluorescence cystoscopy (PDD) or narrow-band imaging (NBI) are emerging new technologies focussing on improved detection of small or flat lesions. NBI is less well studied, thus guidelines statements focus on PDD [22].

7.3 Fluorescence Cystoscopy (Blue Light Cystoscopy)

Fluorescence cystoscopy detects more tumors (both papillary and CIS) than white-light cystoscopy, which has been confirmed by various randomized trials thus improving the tumor identification rate and resulting in better patient management (Table 4) [22].

Enhanced cystoscopy at the times of TUR has been recommended by both AUA and NICE guidelines.

EAU recommends PDD-guided biopsies in the setting of positive cytology but negative cystoscopy.

NCCN does not recommend routine use of PDD-enhanced cystoscopy, citing a lack of evidence regarding reduced progression.

7.4 Narrow Band Imaging

Narrow band imaging is an optical enhancement technology that narrows the bandwidth of the light into 415 and 540 nm and thereby increases the visibility of microvascular structures in the mucosal surface, which are abundant in urothelial tumors.

7.5 Microscopic Imaging Techniques

Optical coherence tomography and confocal laser endomicroscopy provide high-resolution cross-sectional views of vesicular tissues which resemble images obtained for

Table 3 Indication of prostatic urethral biopsies [15]

1. Bladder neck tumor
2. Bladder CIS is present or suspected
3. Positive cytology without evidence of tumor in the bladder
4. Abnormalities of the prostatic urethra are visible

Table 4 Advantages of PDD (blue light cystoscopy) [22]

1	Improve detection rate (particularly CIS)
2	Urinary cytology persistently positive without any demonstrable bladder lesion
3	Reduce residual disease after TUR
4	Decrease recurrences
5	Possibly decrease progression

Table 5 Disadvantages of enhanced cystoscopy

1. Inflammation and scarring lead to a higher false positive rate.
2. Requirement of the special lens system
3. Need to instill the photosensitizer 1 h prior to cystoscopy
4. Rigid rather than flexible cystoscopy
5. Higher cost

histopathological examination. Therefore, these are referred to as "optical biopsy".

7.6 Molecular Imaging

Molecular imaging combines optical imaging with fluorescent labeling of elements such as antibodies offering highly specific real-time visualization of cancer cells and their differentiation from healthy tissue.

The disadvantages and limitations of enhanced cystoscopy are enumerated in Table 5.

8 Radiology

Imaging is an essential component to complete the staging, so as to know the extent of local tumor invasion, and nodal and distant metastasis, and also helps in prognosticating the patients.

8.1 Ultrasonography of the Abdomen and Pelvis

It is considered the first investigating modality to assess the anatomical location and also know the status of the entire urothelial tract. However, it has been replaced by cross-sectional imaging (CT or MRI) for most patients today [23].

8.2 CECT Urography

CT Urography (CTU) should include both the abdomen and pelvis and delayed images to identify defects in the collecting system and is now considered the gold standard for evaluation of patients with initial hematuria presentation (Fig. 2). CT scan is approximately 80 percent accurate in differentiating locally advanced tumors involving extravesical adipose tissue or surrounding structures from less invasive tumors [24]. The role of CTU is limited after TURBT, as it is difficult to distinguish inflammatory or iatrogenic oedematous changes from true extravesical tumor extension.

8.3 MRI for Local Staging of Invasive Bladder Cancer

It has superior soft tissue contrast resolution but poorer spatial resolution compared with CT scans and is considered 73–96% accurate in primary tumor staging. Dynamic contrast-enhanced (DCE) MRI helps in better evaluation of post-biopsy resection cases. VIRADS scoring system has been suggested to evaluate local invasion of bladder tumors. An ongoing randomized trial (BladderPath) is assessing if MRI can reliably predict muscle invasion and obviate the need for doing a TURBT [25].

8.4 Comparison of CT and MRI for Local Staging

The aim of CT and MRI scanning is to detect T3b disease or higher. The perivesical extension is better appreciated on MRI and is recommended for the same. Abdominal nodes >10 mm and pelvic nodes >8 mm in maximum short-axis diameter should be regarded as enlarged on CT and MRI scans. For optimal staging, either MRI with fast dynamic contrast-enhancement or MDCT with contrast enhancement is recommended [26].

8.5 Metastatic Work-Up

Chest radiographs are performed to rule out pulmonary metastases; however, a CT scan is the most sensitive means of detecting pulmonary metastasis.

An isotope bone scan is done to detect bony metastasis and is also useful as a baseline for future reference, particularly in patients with bone pains or increased alkaline phosphatase.

To exclude brain metastasis CT or MRI of the brain should be done if clinically indicated.

8.6 Role of PET-CT Scan in Metastatic Work-Up

PET has limited value and does not yet have an established role in patients with localized bladder cancer due to urinary excretion of 18F-fluorodeoxyglucose (FDG) [27].

Preoperatively, PET/CT is a promising tool to detect metastatic disease, especially in a high-risk disease where the CT or MRI remained inconclusive on distant metastases or in locally advanced bladder carcinoma patients. In a study of 55 patients with bladder cancer, integrated PET/CT improved the preoperative tumor, node, metastasis (TNM) staging compared with CT alone in 15 percent of patients [28].

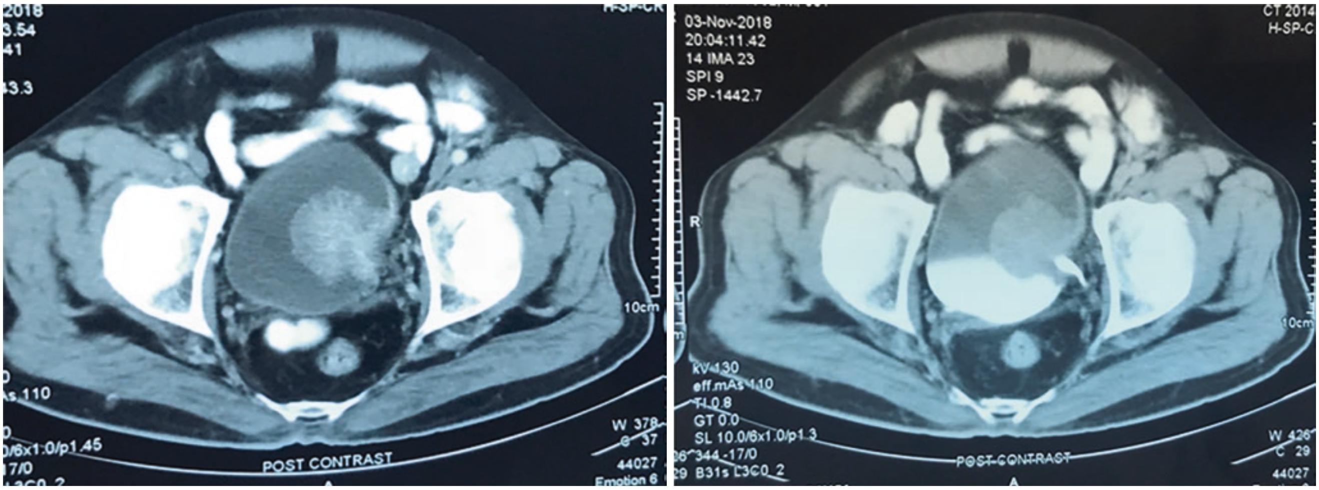

Fig. 2 CECT (IVU) showing large proliferative growth in the left lateral wall with involvement of the left vesico-ureteric junction

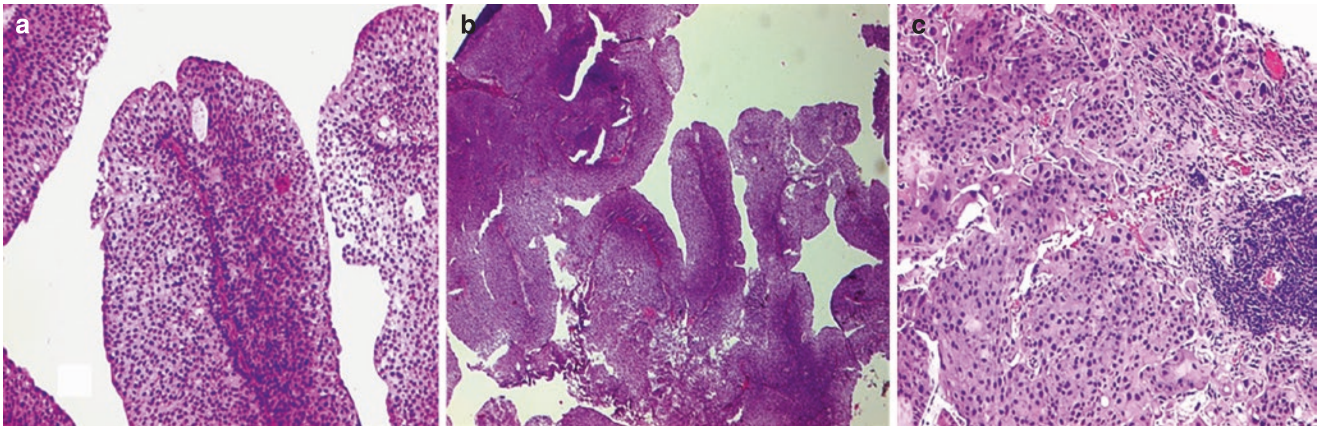

Fig. 3 (**a**, **b**) Microphotograph showing low-grade transitional cell carcinoma. (**c**) High-grade transitional cell carcinoma

9 Pathology

Bladder cancer is a field change and is notorious for multiple recurrences often at new sites. Morphologically a majority (70%) are exophytic papillary tumor confined to mucosa (Ta) or invade submucosa (T1). About 50–70% of NMIBC tumors recur and 5–20% of them progress to invasive disease. Histopathologically, the majority of bladder cancers are urothelial carcinoma (90–95%). Low-grade tumors (G1) have a high local recurrence rate but progression to muscle-invasive disease is low. High-grade NMIBC tumors have a high propensity to transform into invasive tumors which are considered high-grade histologically. (Fig. 3).

Various histological variants exist that are missed on initial transurethral resection specimens (Table 6) [29–31]. Study results showed that analysis of transurethral resection specimens revealed only 39% of cases of histological variants later confirmed at radical cystectomy, and up to 44% of cases of histological variants were not recognized or documented by community pathologists [20].

Table 6 Other histological variants [29–31]

	Histological variants	Incidence (%)
1	Urothelial with squamous differentiation	60
2	Urothelial with glandular differentiation	06
3	Pure squamous cell tumor with keratinization (Schistosomia infestation and chronic irritation)	03
4	Adenocarcinoma (embryonal remnants of urachus)	02
5	Urothelial carcinoma (micro-papillary variant)	0.7–2.2
6	Urothelial carcinoma (nested variant)	–
7	Urothelial carcinoma (plasmacytoid variant)	–
8	Small cell variant	–

9.1 Histological Grading

All available tumor classification still has inherent limitations. The WHO 1973 classification showed Grade 2 tumor had variable presentation between G1/G2 and G2/G3. So, WHO 2004 classification introduced the concept of low-grade and high-grade urothelial carcinoma, which has been

Table 7 Histological grading of bladder urothelial carcinoma [20, 32, 33]

1973 WHO grading urothelial papilloma
• Grade 1: Well differentiated
• Grade 2: Moderately differentiated
• Grade 3: Poorly differentiated
2004/16 WHO ISUP grading
• Papillary urothelial neoplasm of low malignant potential (PUNLMP)
• Low-grade papillary urothelial carcinoma
• High-grade papillary urothelial carcinoma

retained in the WHO 2016 classification also. The WHO 1973 and 2004 classifications have been compared in Table 7 [20, 32, 33]. Staging can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 763–764, Chapter no.62, Urinary Bladder, Table: Definition of TNM and which can be accessed at https://emedicine.medscape.com/article/2006834-overview [34].

10 Genetic Counselling

Bladder cancer is typically not inherited. Most often, tumors result from genetic mutations that occur in bladder cells during a person's lifetime. These non-inherited genetic changes are called somatic mutations.

Spanish bladder cancer study showed that a family history of cancer in first-degree relatives was associated with an increased risk of bladder cancer and showed a stronger association amongst younger patients.

Based only on epidemiological and clinicopathological variables, the important goal of identifying genetic susceptibility loci for cancer risk and outcome is to incorporate them into a comprehensive risk prediction model to improve prediction over currently available models [35].

11 Principles of Management

- Non-muscular invasive bladder cancer (NMIBC) has replaced superficial bladder cancer terminology.
- Properly performed and complete initial transurethral resection of all visible bladder tumours is essential, and an early repeat resection should be performed when indicated.
- Perioperative intravesical chemotherapy decreases recurrence rates by 13%.
- Patients should be risk stratified according to pathology, clinical history, and response to intravesical therapy.
- According to risk stratification, patients should be offered expectant management, intravesical therapy, or radical cystectomy, as appropriate.
- The definitive therapy for muscle-invasive bladder cancer (MIBC) is radical cystectomy or radiation therapy (trimodality) to the bladder.
- A standard template pelvic lymphadenectomy includes the genitofemoral nerves laterally, the internal iliac artery medially, the Cooper ligament inferiorly, and the point at which the ureter crosses the common iliac artery superiorly.
- Based on prospective clinical studies, neoadjuvant cisplatin-based chemotherapy has shown a benefit of 5–10% absolute improvement in 5-year overall survival.
- Patients who did not receive neoadjuvant chemotherapy but have high-risk disease (defined as T3, T4 disease, or presence of nodal metastasis) after radical cystectomy should be considered for adjuvant cisplatin-based chemotherapy.
- Partial cystectomy can be considered in rare, solitary urothelial tumors without concomitant CIS.
- Urachal adenocarcinomas are treated with en-bloc resection of the umbilicus and dome of the bladder.
- The follow-up of non-muscle invasive bladder cancer is based on the principles of regular cystoscopy and urine cytology due to the risk of recurrence and progression.

12 Surgical Management

12.1 Management of Non-muscle Invasive Bladder Cancer

Transurethral resection of bladder tumor (TURBT): Transurethral resection of the bladder tumor(s) is the standard of care for staging bladder tumors and as a part of curative treatment especially in Ta/T1 tumors on pathology. In very small tumors (less than 1 cm) en bloc resection with the underlying bladder wall is the key, whereas larger tumors should be resected in superficial and deep fractions to know the invasiveness of the tumor.

During resection, cauterization of tissue should be avoided to prevent its destruction.

Re-TURBT (Table 8) [22]: Accurate staging of disease is important for optimum treatment and under-staging may lead to inadequate treatment and poor outcomes. Since 33–53% of the patients have residual disease on second resection indicating a significant risk of under-staging in TaT1 tumors and 20% upstaged to the invasive tumor, so second TURBT has shown to increase recurrence-free and progression-free survival. Though there is no consensus regarding the timing of the second TUR, it is generally recommended 2 to 6 weeks after the initial TURBT and should always include resection of the primary tumor site [15, 22].

EORTC after studying the database of 2500 patients developed a scoring system and risk tables to predict the risk

Table 8 Recommendations for the performance of Re-TUR [22]

1	Incomplete initial resection
2	High-risk (recurrent, multifocal, >3 cm)
3	HG pTa tumor (high-grade tumor)
4	Any T1 tumor—resection to include detrusor muscle
5	Detrusor muscle not sampled in the initial specimen—except tag1 and primary CIS or
6	Presence of LVI

Table 9 Prognostic factors for recurrence and progression [22]

High-grade or poorly differentiated tumors (G3)
Co-existent CIS or dysplasia in random mucosal biopsies
Multiple or multicentric tumors
Multiple recurrences within a short period of time (rapidly recurrent tumors)
Lamina propria invasion (T1)
Tumor size of more than 3 cm
Prostatic urethral involvement

of recurrence and progression separately in individual patients.

Table 9 enumerates the factors governing recurrence and progression. Despite an adequate transurethral resection, nearly 70–80% of patients will have a relapse within the bladder while 20–25% will progress to muscle invasion.

Based on tumor grade, size, number, and prior recurrences, NMIBC is risk-stratified (Table 10). Bladder cancer with a low risk of recurrence or progression can be managed by close surveillance and regular check cystoscopy, while those with a high risk of relapse need intravesical chemotherapy or immunoprophylaxis. Table 11 mentions the recommendation for intravesical therapy based on risk stratification.

12.2 Single Post TURBT Instillation

A single immediate post-operative instillation of chemotherapy is recommended in all patients irrespective of the risk group, provided there is no perforation or bleeding.

Timing of the instillation is crucial and is recommended within 24 h (preferably within 6 h).

Meta-analysis of seven RCTs supports the use of single post-operative instillation as recurrence rates are decreased by 12%.

As the recurrence rate is very low after single instillation immediately after TURBT in low-risk group papillary tumors, no further treatment is advised. Intermediate- and high-risk patients require a further 4–8 weeks course of intravesical therapy.

Mitomycin C (MMC), epirubicin, and doxorubicin have all shown comparable beneficial effects. Table 12 [36] enumerates the principles for perioperative intravesical therapy.

Table 10 Risk stratification for non-muscle invasive bladder cancer [22]

Low risk	Intermediate risk	High risk	Highest risk subgroup
PUNLMP	Solitary low-grade Ta > 3 cm	High-grade T1	T1G3/HG associated with concurrent bladder CIS
Low-grade solitary Ta </= 3 cm	Multifocal low-grade Ta	Recurrent high-grade Ta	Multiple and/or largeT1G3/HG
No CIS	Recurrence within 1 year of low-grade Ta	High-grade Ta > 3 cm	Recurrent T1G3/HG
–	All tumors not categorized as low or high risk	Multifocal high-grade Ta	T1G3/HG with CIS in the prostatic urethra
–		Any CIS	Some forms of variant histology of urothelial carcinoma
–	–	Any BCG failure in high-grade cases	LVI positive
–	–	Any variant histology	–
–	–	Any LVI	–
–	–	Any high-grade prostatic urethral involvement	–

Table 11 Recommendations for intravesical therapy in non-muscle invasive bladder cancer [22]

All patients	Single-instillation of intravesical chemotherapy within 24 h of TUR (exception perforation or bleeding)
Low-intermediate-risk	Single instillation of intravesical chemotherapy post-TUR
Low-risk:	Do not offer induction chemotherapy
Intermediate-risk	Consider induction chemotherapy or immunotherapy Maintenance may be utilized in those that respond to induction chemotherapy Maintenance should be considered for 1 year in those that respond to induction BCG
High-risk	Administer induction BCG and continue maintenance BCG for 3 years, as tolerated
Tis	BCG induction with maintenance

12.3 Additional Adjuvant Intravesical Therapy

The need for further adjuvant chemotherapy or BCG immunotherapy largely depends on the risk of recurrence or progression (Table 13) [15, 37].

Table 12 Perioperative intravesical therapy to prevent tumor implantation [36]

Single-dose intravesical chemotherapy administered within 6 h of resection reduces recurrence of low-risk tumors, with significant impact in the setting of initial presentation of solitary low-grade papillary tumors
The incremental benefit in patients with recurrent or multiple tumors is limited
No benefit has been found in patients with high-grade disease

Table 13 Role of adjuvant intravesical BCG (immunotherapy) [15, 37]

1	Intravesical BCG has higher efficacy and side effects compared to intravesical chemotherapy
2	BCG is the only agent shown to delay or reduce high-grade tumor progression reduces the need for cystectomy, increase the time to cystectomy, and improve survival
3	For intermediate and high-risk diseases, maintenance BCG is advised to achieve the best results, provided patients can tolerate it
4	The meta-analysis concluded that at least 1 year of maintenance BCG was required to show the superiority of BCG over MMC in preventing recurrence or progression

A meta-analysis of the MRC and EORTC data comparing intravesical chemotherapy to TURBT alone demonstrated that chemotherapy prevents recurrence but not progression [38].

Four meta-analyses have confirmed the role of BCG after TURBT is superior to TURBT alone or TURBT and chemotherapy in preventing recurrences of TaT1 tumors.

The efficacy of intravesical chemotherapy in reducing the risk of recurrence was demonstrated in the primary as well as recurrent settings by 2 meta-analyses by Huntcharek in 2000 and 2001.

Since there is no optimum BCG schedule with optimal dose yet undefined based on high-level evidence, most centers follow the schedule described by Lamm. The EORTC meta-analysis of nearly 5000 patients demonstrated that there is a 27% reduction in the rate of progression after intravesical BCG treatment in both TaT1 and CIS disease. Weekly instillations for 6 weeks are a commonly used empirical schedule. To reduce BCG toxicity, several authors have proposed a dose reduction of BCG to one-third to one-fourth of the standard dose. The Spanish Oncology Group (CUETO) compared the standard dose with a one-third dose of BCG in a randomized trial and did not find any difference in efficacy, except in patients with high-risk prognostic groups [39, 40]. Table 14 enumerates the contraindications of intravesical BCG.

Table 14 Contraindications of intravesical BCG [38]

Absolute contraindications	Immunosuppressed and immunocompromised patients
	Personal history of BCG sepsis
	Gross hematuria (intravasation risk post TUR)
	Traumatic catheterization (intravasation risk post-TUR)
	Total incontinence
Relative contraindications	Urinary tract infections
	Liver disease
	Personal history of tuberculosis
	Advanced age
	Poor overall performance status

12.4 Recommended Strategies for Treatment of BCG Failure

BCG failures comprise refractory, relapsing, unresponsive disease and intolerant patients (Table 15). BCG toxicity is a common scenario in BCG failure cases. Radical cystectomy is considered the standard-of-care for these patients.

Salvage therapeutic strategies for BCG failures unfit or unwilling to undergo surgery comprise intravesical chemotherapy, chemoradiation, or chemohyperthermia.

Intravesical chemotherapy: Various agents used are valrubicin, gemcitabine, and intravesical taxanes (docetaxel, paclitaxel). Valrubicin is the only approved option for BCG-refractory patients with CIS if cystectomy cannot be performed. Gemcitabine and Docetaxel have been used as salvage mono chemotherapy agents with 1-year disease-free response rates varying from 21% to 50% in various series. Combination chemotherapy regimens like intravesical gemcitabine followed by intravesical docetaxel with 6 weekly induction and monthly maintenance for 2 years has 1- and 2-year response rates of 54% and 34%, respectively. Similar response rates were reported with a combination of intravesical gemcitabine with mitomycin C (MMC), but response rates significantly decline after 2 to 5 years [41].

Chemohyperthermia: It includes delivery of hyperthermic intravesical chemotherapy (HIVEC) with temperatures of 41 to 44 °C. The hypothesized mechanism is that there is a direct cytotoxic effect and hyperthermia enhances the penetration of chemotherapeutic agents into the bladder wall with hyperthermia. In NMIBC, chemohyperthermia is combined with the instillation of MMC, which displays greater toxicity under increased temperature, thereby enhancing its effects. Hyperthermia can be applied to the bladder with different modalities and different devices (Synergo, Combat,

Table 15 Classification of BCG failures [20]

Classification of BCG failures	Definition	Treatment
Adequate *BCG treatment	Patients receiving at least five of six planned instillations of induction treatment and at least two of three planned instillations of maintenance treatment over 6 months	–
BCG refractory	Persistent high-grade disease at 6 months after adequate BCG induction and maintenance treatment or any progression in stage at 3 months assessment (i.e. after induction BCG cycle	Radical cystectomy Bladder-preserving strategies in patients unsuitable for radical cystectomy
BCG relapsing 1. Early relapse: <12 months 2. Intermediate relapse: 12–24 months 3. Late relapse: >24 months	Recurrence of high-grade disease after a disease-free interval of > = 6 months after adequate BCG induction and maintenance treatment	Radical cystectomy Bladder-preserving strategies Repeat BCG course
BCG unresponsive	Included BCG relapsing and BCG refractory. BCG relapsing patients should have a recurrence within 6 months of the last BCG exposure. The highest risk of recurrence and progression	–
BCG intolerant	The disease is persistent because the patient cannot receive adequate BCG owing to BCG toxicity	Radical cystectomy is recommended Alternate intravesical therapy

Unithermia), among which the Synergo system is based on radiofrequency-induced hyperthermia, is the most frequently used. Reported recurrence-free rates for chemohyperthermia vary between 40% and 60% after 2 years; however, data on long-term outcomes are missing [41, 42].

Immune checkpoint blockade: The preliminary results of single-arm KEYNOTE-057 phase II trial (NCT02625961), in which the anti-PD-1 antibody pembrolizumab istested in patients unresponsive to BCG who are considered ineligible for or have refused to undergo radical cystectomy. After a median follow-up of 15.8 months, the complete response rate was 40.2%, with a median CR duration of 12.7 months. 36.6% of patients developed recurrent NMIBC after having a complete response and no patients progressed to muscle-invasive disease/metastatic disease. A phase 3 study evaluating pembrolizumab in high-risk non-muscle invasive bladder cancer that is persistent after BCG induction (KEYNOTE 676) is underway. Several trials are currently ongoing with anti-PD-L1 antibody atezolizumab, alone or in combination with BCG and nivolumab an IDO-1 inhibitor or BCG (CheckMate 9UT, NCT03519256), or durvalumab (NCT02901548) [43].

Table 16 Cleveland clinic approach for complications associated with intravesical BCG administration [45]

Grade 1: moderate symptoms < 48 h Mild or moderate irritative voiding symptoms, mild hematuria, fever <38.5 °C	Symptomatic management Anticholinergics, topical antispasmodics (phenazopyridine), analgesics, nonsteroidal anti-inflammatory drugs
Grade 2: severe symptoms and/or > 48 h Severe irritative voiding symptoms, hematuria, or symptoms lasting >48 h	Consider dose reduction to one-half to one-third of the dose when instillations resume Administer isoniazid and rifampicin, 300 mg/day and 600 mg/day, orally until symptom resolution
Grade 3: Serious complications (hemodynamic changes, persistent high-grade fever)	Isoniazid, 300 mg/day, and rifampicin, 600 mg/day, for 3–6 months depending on the response

Mycobacterium phlei cell wall nucleic acid complex (MCNA): It is an immunotherapeutic agent derived from M. phlei that has been used in BCG-refractory or BCG-relapsing patients. Recently, in a single-arm phase III trial with 129 BCG failure patients treated with induction and maintenance MCNA, recurrence-free survival rates of 25% after 12 months and 19% after 24 months were reported.

Viral gene therapies and targeted therapies are currently tested in several clinical trials in patients after BCG failure. Interim results are encouraging and selected approaches might be added to the physician's armamentarium for bladder-sparing options after BCG failure in the future [43, 44].

Table 16 classifies BCG toxicity and its management [45].

12.5 Cystectomy for Non-muscle Invasive Bladder Cancer

Despite intravesical adjuvant therapies, there is a substantial group of patients with initial high-grade stage T1 tumor who have progression and are at risk of dying from urothelial cancer. It is reasonable to propose immediate cystectomy to those patients who are at high risk of progression (multiple recurrent high-grade tumors, high-grade T1 tumors, high-grade tumors with concomitant CIS). Cystectomy is advocated in patients with BCG failure and delaying cystectomy in these patients may lead to decreased disease-specific survival [15].

12.6 Management of Carcinoma-In-Situ

Carcinoma in situ of the bladder may exist alone (primary CIS) or in combination with a bladder tumor. Primary CIS confined to the bladder is treated with intravesical BCG, with excellent complete response rates of 82–93%. Recurrence of primary CIS despite the first course of BCG may be treated with a second course of BCG with a response seen in 40–50% of patients. CIS associated with an overt tumor is treated according to the merits of the tumor. Approximately 50% of patients develop the recurrent disease with muscle invasion or extravesical tumor, and 10–20% die of their disease within 5 to 7 years after an initial complete response. Non-responders or incomplete responders have a significant risk of tumor progression and cystectomy is recommended in such patients. Patients with an incomplete response at 9 months, recurrent tumors, or extravesical disease also need cystectomy [15]. Table 17 classifies CIS as per clinical type [15, 46].

12.7 Follow-Up Schedules in NMIBC

Prompt detection of muscle-invasive and high-grade non-muscle-invasive recurrences is critical and delay in diagnosis and therapy could compromise survival. Tumor recurrence in a low-risk group is nearly always low-stage and low-grade and does not pose a threat to life. High-risk patients may present as muscle-invasive disease on recurrence and need immediate diagnosis and treatment. The result of the first cystoscopy after TUR at 3 months is an important prognostic factor for recurrence and progression and hence cystoscopy at 3 months post-TUR is recommended in all patients [22]. The follow-up protocol for NMIBC is summarized in Table 18.

12.8 Management of Muscle-Invasive Bladder Cancer

Newly diagnosed bladder cancers have muscle invasion in approximately 30% of cases. Besides, 20–25% of NMIBC bladder cancer progress to muscle invasion sometime during their natural history. Approximately 30% of patients diagnosed with muscle-invasive bladder cancer have undetected metastasis at the time of treatment of a primary tumor, while 25% of patients submitted to radical cystectomy present with lymph node involvement at the time of surgery [15].

Table 17 Classification of CIS according to clinical type [15, 46]

Classification	Definition
Primary CIS	Isolated CIS with no previous or concurrent papillary tumors and no previous CIS
Secondary CIS	CIS detected during follow-up of patients with a previous tumor that was not CIS
Concurrent CIS	CIS in the presence of any other urothelial tumor in the bladder

Table 18 Surveillance recommendations for bladder recurrence in non-muscle invasive bladder cancer [22]

Risk stratification	Follow up schedule
All patients	Initial cystoscopy within 3–4 months of completion of treatment
Low-risk:	Cystoscopy 6–9 months later, and then annually for at least 5 years
Intermediate-risk	Cystoscopy + cytology every 3–6 months for 2 years, then every 6–12 months for years 3–4, and then annually thereafter
High-risk:	Cystoscopy + cytology every 3–4 months for 2 years, then every 6 months for years 3–4, and then annually thereafter
Upper tract evaluation	Yearly for high-risk NMIBC, no specific recommendations for low- or intermediate-risk NMIBC Not routinely recommended for low-risk NMIBC

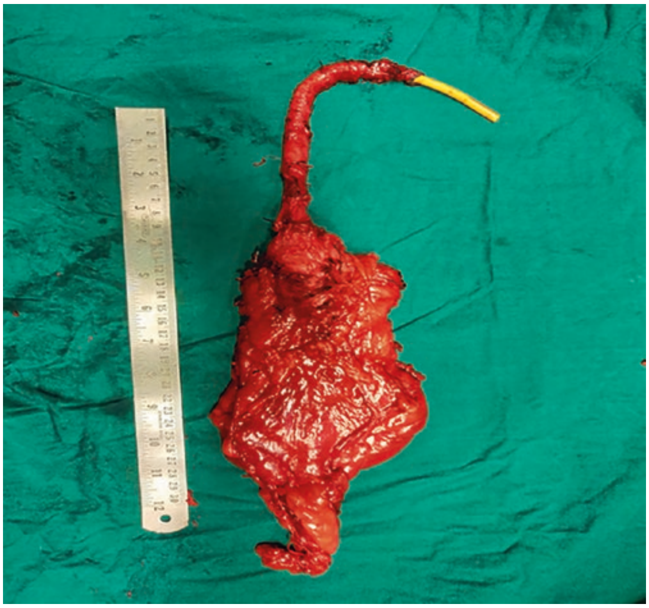

Fig. 4 En bloc specimen of radical cystoprostatectomy with urethrectomy

12.8.1 Surgery

Radical cystectomy is the preferred treatment for invasive bladder cancers in patients whose medical condition allows the major surgical procedure (Fig. 4). Pelvic lymphadenectomy is routinely performed as part of radical cystectomy for bladder cancers; however, there is a lack of consensus on the intent (therapeutic or staging/prognostic) and extent of lymph node dissection (Fig. 5). There is evidence from retrospective studies that extended lymphadenectomy improves outcome in patients with tumors confined to the bladder. However, no controlled

Right Internal iliac Artery
Right External iliac artery
Right Obturator nerve
Right External iliac Vein
B

studies support extended lymphadenectomy as a curative treatment. Thus, limited or regional lymph node dissection is the recommended standard surgical method (Table 19) [47, 48]. Removal of more than 15 lymph nodes has been postulated to be both sufficient for the evaluation of the lymph node status as well as beneficial for overall survival in retrospective studies in the presence of gross nodal disease [15, 48].

Radical cystectomy is recommended for non-transitional cell carcinomas, which generally respond less to radiation and chemotherapy. However, despite adequate surgery, approximately 50% of patients will develop metastatic disease within 2 years, emphasizing the need for augmenting treatment in these patients. The 5-year survival rates after radical cystectomy alone in T2, T3a, T3b, and T4 disease are 63%, 57%, 31%, and 18%, respectively.

Partial cystectomy is very rarely indicated in muscle-invasive urothelial cancer. Patients, who are not fit for radical cystectomy with solitary muscle-invasive tumor at the dome, with no extravesical spread and negative random mucosal biopsies and intra-operative frozen section surgical margins can be considered for partial cystectomy.

12.9 Indications of Urethrectomy [49]

Urethrectomy may be done at the time of cystectomy or subsequently as a separate procedure in the following scenarios

1. A tumor involves the bladder neck in women or the prostatic urethra in men.
2. The positive urethral cut margin at the end of cystectomy.
3. Extensive involvement of the prostate stroma.

Table 19 Extent of lymph node dissection in bladder cancer [47]

Type of lymph node dissection	Definition
Limited	Lateral boundary: External iliac vein Medial boundary: Obturator nerve (Perivesical tissue and lymphatic tissue in obturator fossa)
Standard	Superiorly: bifurcation of the common iliac artery Inferiorly: circumflex iliac vein Medially: Internal iliac vessels Laterally: Genitofemoral nerve Floor: obturator fossa
Extended	Proximal boundary: crossing of ureter /common iliac artery. Rest landmarks as a standard template
Super extended	Proximal boundary: the origin of IMA. Rest landmarks as a standard template

12.10 Urinary Diversion or Reconstruction

The type of urinary diversion does not affect the oncological outcome. The advantage of orthotopic neobladder over other diversions in terms of quality of life remains a matter of debate. The terminal ileum and colon are the intestinal segments of choice for urinary diversion. The morbidity of orthotopic neobladder reconstruction is appreciable in terms of major complications and reoperation rates. Orthotopic neobladder reconstruction should be advised to suitable patients after cystectomy for organ-confined muscle-invasive bladder tumor. While discussing this option with the patient, the morbidity must be addressed [49].

Table 20 Classification of urinary diversion

Classification	Type of urinary diversion
1. Orthotopic	Orthotopic bladder substitution 1. Studder neobladder 2. Hautmann neobladder 3. Mainz neobladder
2. Heterotopic (a) Continent	1. Cutaneous (catheterizable stoma on the abdominal wall) Types: (a) Right colonic pouch (Indiana pouch, Florida pouch, Miami pouch, Penn pouch) (b) Ileal pouches (Koch ouch, Mainz pouch)
(b) Non-continent	1. Ileal conduit/colonic conduit/ jejunal conduit 2. Cutaneous ureterostomy
(c) Diversion to the gastrointestinal tract	1. Uretero-sigmoidostomy/rectal bladder

Table 21 Oncological principles of orthotopic neobladder reconstruction [50]

1	The patient must have a healthy urethra and adequate external sphincter function to maintain continence
2	The bowel segment should be de-tubularized and reconstructed into a spherical shape.
3	Ultimate storage volume should be at least 300 to 500 mL at low pressure

Table 22 Contra-indications to orthotopic neobladder

1. Prostatic urethral involvement
2. Positive urethral margins
3. Multiple bladder tumors or multicentric involvement of the urinary tract
4. Chronic kidney disease

The various options available are as follows:

- Incontinent conduit with an external stoma.
- Continent catheterizable reservoirs with an abdominal stoma.
- Bladder substitution (neobladder) procedures.

Table 20 classifies the types of urinary diversion. Table 21 [50] enumerates the principles governing orthotopic neobladder reconstruction. Table 22 and Table 23 enumerate the contraindications to neobladder reconstruction and management of morbidity related to neobladder.

Table 23 Management of neobladder morbidity (30–64%) [46]

Complications	Management
Immediate complications:	
Post-operative nausea and vomiting	1. Anti-emetic agent (decrease opioids) 2. Nasogastric intubation
Post-operative ileus	1. Chewing gum 2. Nasogastric intubation 3. Avoid fluid excess and hypovolemia
Ureteral catheter obstruction	1. Inject 5 cc saline in the ureteral catheter or 2. Increase volume infusion to increase diuresis
Urinary infection	1. No ureteral catheter removal and check the 3 drainages (ureters and neobladder) 2. Antibiotics
Uretero-ileal anastomotic leak	1. Check drainages 2. Watchful waiting
Anaemia	1. Iron supplements
Late complications:	
Incontinence	1. Urine analysis 2. USG (post-void residue) 3. Physiotherapy
Retention	1. Drainage 2. Self-catheterization education
Pyelonephritis	1. Antibiotics 2. Renal drainage (nephrostomy if necessary)
Pulmonary embolism	1. Heparinotherapy
Anastomosis stenosis (7%)	1. Renal drainage (ureteral catheter or nephrostomy)
Compressive lymphocele	1. Surgery (marsupialisation)
Ileal anastomosis leakage	1. Ileostomy, as soon as possible

12.11 Enhanced Recovery after Surgery Pathway Outcomes

ERAS study group was formed in 2001 with an emphasis on improving and standardizing perioperative care. In the setting of radical cystectomy, ERAS has shown benefits in reducing the incidence of postoperative especially gastrointestinal complications, and also shortens the length of hospital stay. So, continuous modifications of the ERAS pathway will help us in refining patient care and improve postoperative outcomes [51].

13 Minimally Invasive Surgery for Bladder Cancer

RARC as a minimally invasive technique is gaining wide acceptance, which seems non-inferior to open radical cystectomy. To date, randomized controlled trials comparing open with robotic- assisted radical cystectomy have shown lower estimated blood loss, lower blood transfusion, long operative time with similar oncologic outcomes, increased cost, decreased length of hospital stay, and similar perioperative complications. Hence, it is a technique that should complement and not substitute oncologic principles [52].

The RAZOR trial (Randomized Open Versus Robotic Cystectomy multi-institutional trial) has shown an increased presence of positive soft tissue margin in the initial learning curve, which is supposed to be a strong marker of poor prognosis but as the learning curve increases, the percentage of cases with positive margins decreases [53].

Robotic radical cystectomy with intracorporeal urinary diversion is the latest addition to the surgical armamentarium.

Additionally, robotic surgery has the distinct benefit of higher magnification and surgeon's comfort but the availability of robots and cost is a concern.

14 Role of Chemotherapy in Bladder Urothelial Carcinoma

14.1 Neoadjuvant Chemotherapy Before Radical Cystectomy

Although radical cystectomy is the standard treatment for patients with muscle-invasive bladder cancer, it leads to long-term cures in only 50% of patients. In order to improve these results, the use of neoadjuvant chemotherapy has been explored. The rationale for chemotherapy is based on the intention to treat micrometastatic disease, which is present at diagnosis prior to cystectomy or radical radiation therapy. Neoadjuvant chemotherapy administered before definitive local treatment (surgery or radiotherapy) has shown a survival benefit based on a meta-analysis of 3005 patients from 11 randomized trials. A meta-analysis showed that neoadjuvant chemotherapy decreased the risk of death by 14%, improved absolute disease-specific survival by 9%, and improved overall survival by 5% at 5 years ($p = 0.003$). This advantage in survival was seen for all muscle-invasive tumors and only patients who received a cisplatin-containing regimen benefited. Though the available data support the use of M-VAC (methotrexate, vinblastine, doxorubicin, and cisplatin) or CMV (cisplatin, methotrexate, vinblastine) as neoadjuvant chemotherapy, these regimens are less frequently used as phase 3 data in the metastatic setting suggested that a less toxic regimen of gemcitabine and cisplatin (GC) has similar efficacy to M-VAC. Neoadjuvant chemotherapy is not recommended in patients with poor performance scores and impaired renal function [20, 54].

14.2 Adjuvant Therapy

To date, there have been five published randomized trials of adjuvant chemotherapy and one meta-analysis, neither has provided sufficient data to support the routine use of adjuvant chemotherapy. The commonest regimens used are MVAC/CMV or CISCA. Although not convincingly shown to improve survival, it may be useful in patients with pT3–4 and/or N+ patients [20, 50].

14.3 Chemotherapy for Metastatic Bladder Cancer

Approximately 5–10% of bladder cancers are metastatic at presentation and another 40% of patients will develop metastatic disease during their clinical course, typically appearing in lymph nodes, lung, liver, or bone. Patients with good PS, adequate renal function, and only lymph nodal metastasis are considered as the best candidates for chemotherapy with approximately 15% having long-term survival. Methotrexate, vinblastine, doxorubicin (Adriamycin), cisplatin (M-VAC), and gemcitabine/cisplatin (GC) have prolonged survival up to 14.8 and 13.8 months, respectively. Since single-agent chemotherapy has shown low response rates, So, combination M-VAC chemotherapy is considered superior due to high response rates. Carboplatin combination chemotherapy is less effective than cisplatin-based chemotherapy in terms of CR and survival. Either M-VAC or CMV has been considered the standard combination for metastatic bladder cancer. In an international randomized trial, M-VAC was compared with gemcitabine and cisplatin (GC). Both arms were found to be equivalent in terms of response rates, time to treatment failure, time to progressive disease, and overall survival. GC appeared to have a reduced toxicity profile as compared to M-VAC, making GC a new standard chemotherapeutic option in patients with metastatic bladder cancer. Second-line therapy should be considered within a clinical trial setting. If the patient has a good PS, single agents or paclitaxel/gemcitabine may be considered. Quality of life issues are very important considerations when deciding on further chemotherapy [20, 55, 56].

Table 24 Role of immunotherapy in metastatic urothelial carcinoma [20]

Study population	Immunotherapy drug	Target	Response rate (%)	Median progression-free survival (months)	Median overall survival (months)
Metastatic urothelial carcinoma	Gemcitabine plus cisplatin and ipilimumab	CTLA-4	23/36 (64%)	–	14.6
Muscle-invasive bladder cancer	Ipilimumab	CTLA-4	–	–	–
Post platinum therapy metastatic urothelial carcinoma	Atezolizumab	PD-L1	45/310 (15%) 26/100 (26%)	2.1	7.9
Post platinum therapy metastatic urothelial carcinoma	Pembrolizumab	PD-L1	8/29 (28%) 6/18 (33%)	2	12.7

14.4 Emerging Bladder Cancer Treatments

Bladder cancer has seen a substantial increase in drug development activity in the past 5 years. Recent developments in the field of immunotherapy have shown some rays of hope in the post-platinum era in terms of good response rates, especially in platinum-resistant cases or those patients who are ineligible for cisplatin owing to renal impairment or other medical comorbidities (Table 24) [20].

15 Role of Radiotherapy

For stage Ta, T1, or Tis disease, adjuvant radiation is not indicated [57]. However, in recurrent Ta-T1 disease after BCG therapy but without extensive Tis who are not candidates for cystectomy, concurrent chemoradiotherapy is a valid alternative with comparable outcomes [58, 59].

15.1 Bladder Preservation

For T2-T3 muscle-invasive bladder cancer, the standard treatment had been radical cystectomy. But now, there is evidence [59–61] to show similar survival outcomes with up to 80% bladder preservation rate and limited grade III/IV toxicities using trimodality treatment which comprises radiotherapy, chemotherapy, and surgery. This involves neoadjuvant chemotherapy followed by maximal Transurethral resection of bladder tumor (TURBT) followed by radical radiotherapy with concurrent chemotherapy, reserving cystectomy as a salvage option. Older series [59] have shown a good response to radiotherapy alone in patients unfit for surgery. However, outcomes of bladder preserving CTRT are expectedly better in patients with good bladder function pre-radiotherapy, without extensive CIS or tumor-related hydronephrosis.

In the best hands, overall survival rates with bladder preservation are comparable to radical cystectomy [62, 63]. Pooled analysis of 6 RTOG trials with clinical T2 to T4a tumors has shown a complete response rate of 69% following chemo-radiotherapy. The 5-year disease-specific survival (DSS) rate was 71% and 5-year OS was 57%. Of the 205 patients alive at 5 years, 80% had intact bladder [64]. Routine follow-up with cystoscopy and exfoliative urine cytology is warranted in view of the high local recurrence rate (36%). Better outcomes have been reported with the addition of concurrent chemotherapy to RT [61].

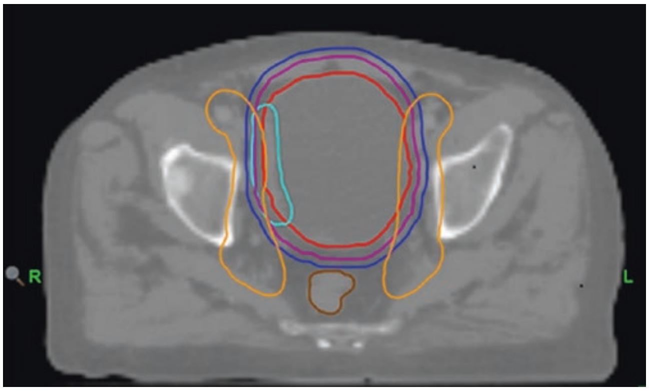

Fig. 6 Axial view of planning CT scan showing the three PTV margins to the bladder

Conformal three-dimensional RT techniques have replaced two-dimensional approaches for radiotherapy delivery (Fig. 6). Intensity-modulated radiation therapy (IMRT) with image-guided radiotherapy (IGRT) has allowed for dose escalation as well as minimizing genitourinary and gastrointestinal toxicities. The dose consists of 60 to 64 Gy to the entire bladder, prostatic or proximal urethra, and 50 Gy to the regional lymph nodes This is followed by restaging cystoscopy. "Plan of the day" is an adaptive radiotherapy technique that involves generating multiple planning target volumes (PTV) using anisotropic margins and treating the patient with the appropriate PTV for that particular day. This ensures the best possible coverage of the bladder resulting in better dose delivery and reduced toxicity to the small bowel [65, 66].

15.2 Role of Adjuvant Radiotherapy

Adjuvant postoperative radiotherapy for pT3 and pT4 bladder cancer patients has been studied in small prospective trials (particularly for squamous cell carcinomas) [67]. Two-year outcomes and overall adjusted hazard ratios (HRs) for chemotherapy plus RT versus chemotherapy alone have been reported 68% vs. 56% (HR, 0.53; 95% CI, 0.27–1.06; $P = 0.07$) for disease-free survival, and 71% vs. 60% (HR, 0.61; 95% CI, 0.33–1.11; $P = 0.11$) for overall survival [68]. The role of adjuvant RT is being currently investigated in large phase III randomized trials [69, 70] including BART (Bladder Cancer Adjuvant Radiotherapy) trial [71] from Tata Memorial Hospital, Mumbai for patients with pT3 and pT4 disease, lymph node positivity, close/positive margin of resection as well as a number of nodes dissected at surgery <10.

Table 25 Recurrence-free and overall survival after radical cystectomy [48]

		Recurrence-free		Overall survival	
Pathologic stage		5 years (%)	10 years (%)	5 years (%)	10 years (%)
pTo, pTa, pTis		88	85	84	67

Extravesical, including pT3b and pT4 bladder tumors

Table 25 shows the recurrence-free and overall survival after definitive local therapy for MIBC.

Palliative RT is used for bone metastasis, pain relief, as well as for achieving hemostasis in advanced, hemorrhagic tumors refractory to anticoagulants. Table 26 enumerates the management options for recurrent disease.

How We Do It at TMC

- Patients are referred to TMC for bladder cancer based on sonography findings of mass in the bladder, or after cystoscopic biopsy of bladder mass or after TURBT of bladder tumor or occasionally with clot retention and gross hematuria.
- Based on available imaging, biopsy, and TURBT histopathology these tumors are suspected to be NMIBC, MIBC, or equivocal.
- All histopathologies reported elsewhere are reviewed by GU pathologists at TMC to confirm concordance of grade, and depth and rule out variant histology.
- Cystoscopic evaluation and mapping of all tumours is done. In patients with definite MIBC or metastatic disease cystoscopy can be skipped. Some patients require emergency clot evacuation and TURBT because of gross hematuria at presentation.
- Patients with obstructive uropathy at presentation undergo unilateral or bilateral nephrostomy which stays till definitive management is done. Retrograde DJ stenting is rarely feasible in these patients.

Table 26 Management of recurrent disease including specific palliative measures [46]

Site of recurrence	Management strategies
Local recurrence	Offer radiotherapy, chemotherapy, and possibly surgery as options for treatment, either alone or in combination.
Distant recurrence	Offer chemotherapy as the first option, and consider metastasectomy in case of a unique metastasis site.
An unresectable tumor (T4b) with bleeding, pain, dysuria, and urinary obstruction	Silver nitrate, alum, formalin instillation, pall RT, angioembolization for bleeding Unilateral/bilateral nephrostomy or DJ stenting for obstructive uropathy Palliative cystectomy with urinary diversion or only urinary diversion as a last resort

- Patients with NMIBC are categorized into low, intermediate or high risk based risk stratification suggested in EAU guidelines.
- All high grade and T1 patients who have undergone TURBT earlier undergo restaging TURBT irrespective of presence or absence of detrusor in initial histopathology.
- Perioperative single instillation of Mitomycin C is done in all patients undergoing TURBT. This is done preferably within 6 h and definitely within 2 h of surgery unless there is a perforation or gross hematuria post-surgery.
- In all intermediate and high-risk patient's induction and maintenance intravesical BCG is instilled as per Lamm's regime. Patients are assessed for BCG toxicity before each instillation.
- Patients with MIBC or very high risk NMIBC or those with variant histopathology are considered for radical cystectomy or bladder preservation.
- GFR estimation of all MIBC patients is done by plasma sampling. Differential GFR is estimated by renogram when required.
- Based on patients GFR and performance status they are evaluated for eligibility of cisplatin-based neoadjuvant chemotherapy. If eligible they undergo three cycles of gemcitabine and cisplatin before undergoing cystectomy.
- Radical cystectomy includes extended pelvic lymph node dissection. Based on disease profile and patient's preference either an ileal conduit or neobladder diversion is constructed. Ileal conduit is the most common diversion done at TMC. All patients get nutrition clinic reference at the time of decision for cystectomy and post-operative stoma clinic reference is also done.
- Patients who could not receive neoadjuvant chemotherapy are considered for adjuvant chemotherapy based on histopathology. Eligible patients are enrolled in Bladder Adjuvant Radiotherapy (BART) trial. They could receive adjuvant radiotherapy if randomized to treatment arm.
- Figure 7 depicts the management algorithm for bladder cancer patients at TMH.
- Surveillance of all NMIBC and MIBC patients is done as per EAU guidelines.
- Patients with metastatic disease are considered for palliative chemotherapy, pain management, nephrostomy, angioembolization, palliative radiotherapy based on their presentation and performance status.

Upper Tract Urothelial Cancer

Kunal Dholakia, Rajesh Reddy, and Gagan Prakash

Abbreviations

BCG	Bacillus Calmette-Guérin
CT	Computerized tomography
FISH	Fluorescence *in situ* hybridization
HNPCC	Hereditary nonpolyposis colorectal carcinoma
HR	Hazard ratio
LNU	Laparoscopic nephroureterectomy
MMC	Mitomycin-C
MRI	Magnetic resonance imaging
PUNLMP	Papillary urothelial neoplasia of low malignant potential
RNU	Radical nephroureterectomy
RT	Radiation therapy
URS	ureteroscopy
UTUC	Upper tract urothelial carcinoma

1 Introduction

Upper tract urothelial cancers (UTUC) include the neoplasms arising from the lining of the urinary tract anywhere between the pelvicalyceal systems to the distal ureter. UTUC share a few similar features with urothelial carcinoma bladder; however, they tend to be rare and more advanced at the time of presentation. Radical nephroureterectomy (RNU) with ipsilateral bladder cuff excision is the gold-standard treatment. However, in recent years, nephron-sparing approaches have been widely gaining popularity, especially in low-risk diseases [1].

2 Incidence and Epidemiology

Nearly all cases of urothelial carcinoma are urinary bladder cancers, whereas UTUC accounts for just 5–10% of all urothelial malignancies. However, ~60% of UTUCs are usually found to be invasive at the time of diagnosis, compared with only 15–25% of bladder tumors. The peak incidence of UTUC is at 75–79 years [2, 3].

The most common location for this tumor is the renal pelvis. When it comes to the ureter, the distal ureter is the most affected part. Based on the location, the incidence of ureteric tumors is as follows: lower ureter in 70%, mid ureter in 25% and then upper ureter in 5% of the cases [4, 5].

Concurrent urothelial carcinoma bladder is seen in 17% of UTUC cases. Recurrence of urothelial tumors in the bladder occurs in 22–47% of the cases and recurrence in the contralateral upper urinary tract is seen in 2–6% [6, 7].

Many environmental and genetic factors are implicated in the development of UTUC.

2.1 Environmental Factors

Tobacco consumption is the most important contributing factor in the development of UTUC. Among smokers, the relative risk for developing upper tract neoplasms is 2.5 to 7-fold higher than that for nonsmokers [8].

Balkan endemic nephropathy, a kind of degenerative interstitial disease, is observed in people living in Balkan countries (i.e., Bulgaria, Greece, Romania and the former Yugoslavia). Dietary exposure to aristolochic acid, which is derived from Aristolochia plants, was found to be the culprit carcinogen. A similar association with the consumption of

Chinese herbal products which contain *Aristolochia fangchi* and Chinese herb nephropathy was postulated. Both the diseases are associated with the development of UTUC. Surprisingly, the incidence of bladder urothelial carcinoma is not affected. Mutation of the p53 gene was found to be a consequence of aristolochic acid exposure [9, 10].

An unusually high incidence of UTUC was also reported from "Blackfoot disease" endemic areas, especially in southern Taiwan. It's a type of vasculitis that occurs due to arsenic-contaminated water [11]. Phenacetin use with papillary necrosis has also been recognized as a risk factor for UTUC [12].

2.2 Genetic Factors

Hereditary nonpolyposis colorectal carcinoma (HNPCC) otherwise called Lynch syndrome is associated with the development of colorectal and endometrial tumors due to various DNA mismatch repair abnormalities. The relative risk of developing UTUC in these cases is 22 folds approximately [13].

3 Clinical Presentation

The common presenting features of UTUC are microscopic or macroscopic hematuria (56–98%), loin pain (20–40%) and lumbar mass (10–20%). About 15% of patients are incidentally detected [14].

4 Evaluation and Work-up

4.1 Imaging

4.1.1 Ultrasonography (USG)

The detection rate of renal pelvis carcinoma using the USG is moderate (82%). But detection of ureteric tumors can be as low as 12%. However, the USG can demonstrate secondary signs caused by ureteric tumors such as dilatation of the ureter and pelvicalyceal system [14].

4.1.2 Computerized Tomography (CT)

Multiphasic CT urography yields the maximum diagnostic accuracy for upper tract neoplasms with a sensitivity and specificity ranging from 0.67 to 1.0 and 0.93 to 0.99, respectively. It can also detect urolithiasis and renal tumors; hence, it has become the gold-standard investigation for hematuria evaluation (Fig. 1). However, flat upper tract lesions can be missed on CT. Ureteric wall thickening and periureteric fat stranding if present are red flags in such cases [15, 16].

4.1.3 Magnetic Resonance Imaging (MRI)

MRI is useful in individuals who cannot undergo CECT due to contraindications related to radiation exposure or iodinated contrast administration. Documented sensitivity of contrast MRI for tumors <2 cm is 0.75. MRI is unreliable in detecting urolithiasis, which is a major limiting factor for being a primary imaging modality for hematuria. Similar to CT scans, MRI can also miss flat lesions because of motion artifacts [14, 16].

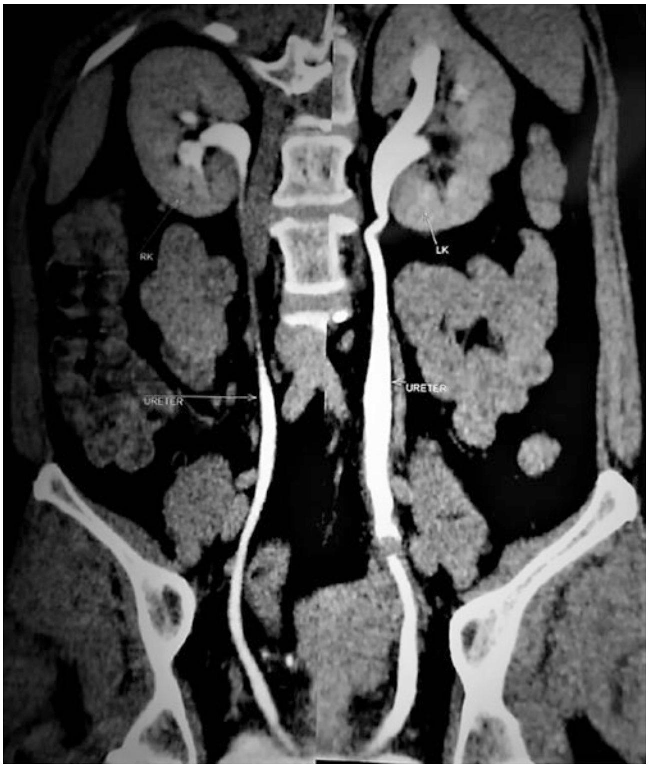

Fig. 1 CT scan showing left ureteric tumor (Arrow head)

4.2 Endoscopy

Clinicians should have a high index of suspicion for UTUC when cystoscopy is normal with positive urine cytology. In such a scenario, selective ureteric catheterization followed by barbotage or brushing is performed. The sensitivity of ureteral washing and brushing in detecting UTUC is 80% and 90%, respectively. Additionally, retrograde urethrography can help to identify any filling defects, often known as the "goblet sign" (Fig. 2). Selective urine samples for cytology should be collected before retrograde urethrography because administration of hyperosmolar contrast material can cause alteration of the microscopic cytology features of the tumor cells [5, 17].

Recent improvements in endoscopic technology including fiber optics and flexible ureteroscopes with active deflection are allowing better visualization of the urinary tract and if needed, a biopsy of the suspected lesions (Fig. 3). The specificity of ureteroscopic biopsy to determine the tumor grade is between 75% and 92%. However, accurate assessment of tumor invasion is very difficult [14, 18].

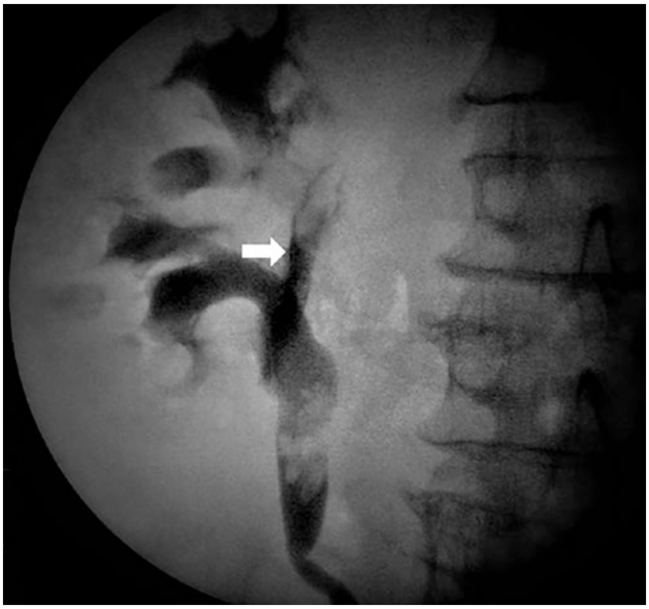

Fig. 2 RGU showing filling defect in right upper ureter (Arrow head)

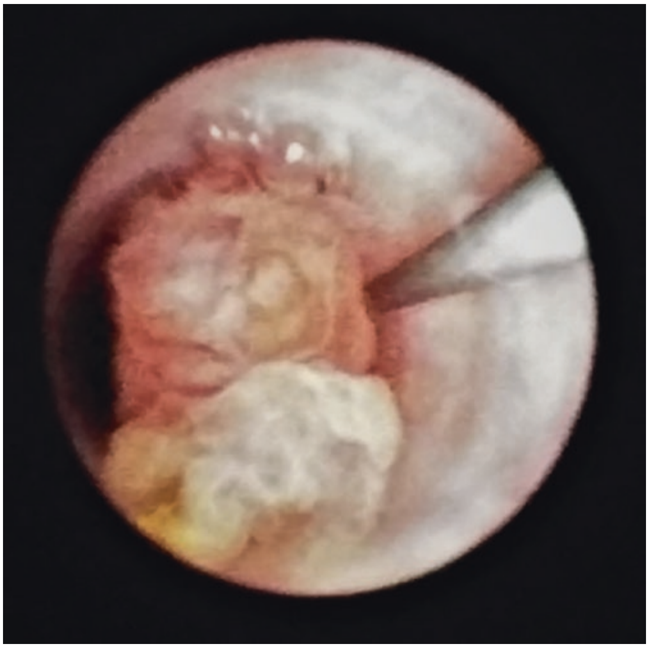

Fig. 3 Ureteroscopic view of ureteric tumour

4.3 Tumor Markers

Urinary cytology for UTUC is generally less sensitive than it is for urothelial carcinoma bladder. However, ureteric washings improve the diagnostic yield. Fluorescence *in situ* hybridization (FISH) appears to be more sensitive than urinary cytology and has equal specificity in detecting UTUC [19]. The nuclear matrix protein (NMP22) test has better sensitivity but lower specificity than urinary cytology [20].

4.4 Pathology

The UTUCs can manifest as noninvasive papillary tumors, carcinoma *in situ* (CIS; High-grade flat lesion) and invasive tumors. These lesions share similar features with bladder urothelial carcinoma on histology. However, early muscle invasion or periureteric spread can happen because of the relative thinness of the muscle layer of the upper urinary tract when compared with the bladder. WHO-2004 grading distinguished three kinds of noninvasive neoplasms, i.e., papillary urothelial neoplasia of low malignant potential (PUNLMP), low-grade carcinomas and high-grade carcinomas. Benign urothelial papillomas are excluded from this classification [21].

Variants of urothelial carcinoma include squamous cell, glandular, sarcomatoid, micropapillary, neuroendocrine and lymphoepithelial tumors. Their incidence is as high as 25% of upper tract neoplasms. Variants are considered to be relatively aggressive tumors [22].

The TNM classification 2017 is the presently used standard staging system and can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 754, Chapter no. 61, Renal Pelvis and Ureter, Table: Definition of TNM which can be accessed at https://www.pathologyoutlines.com/topic/bladderstagingrenalpelvis.html

When it comes to Renal pelvic tumors, invasion into the renal pelvis is classified as T3 disease. Subclassification of this category may differentiate between microscopic (pT3a) versus macroscopic (pT3b) renal parenchyma infiltration or invasion of peripelvic adipose tissue [23].

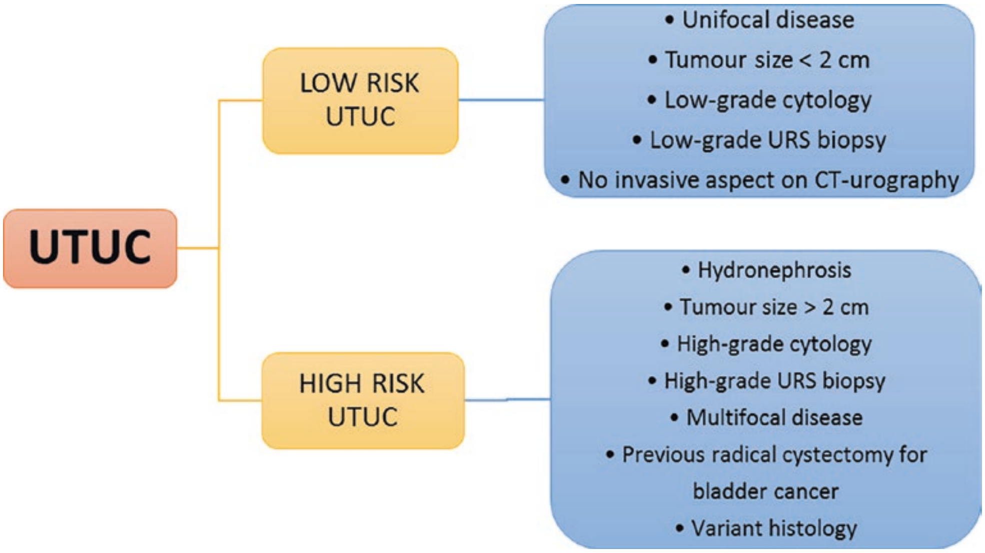
4.5 Genetic Counseling

HNPCC (Lynch syndrome) must be suspected in individuals of UTUC at a younger age at presentation or personal/family history of HNPCC spectrum of disorders. These patients subsequently should undergo germline DNA sequencing to confirm the diagnosis. Once HNPCC syndrome is diagnosed, the key to management is good surveillance to prevent disease recurrence as well as the screening of first-degree relatives for the HNPCC spectrum of diseases [24].

5 Principles of Management (an Integrated Brief Overview of Rx Philosophy)

The management of upper tract urothelial tumors has changed significantly lately. Numerous prognostic factors have helped to guide therapy and predict survival outcomes. Technologic advancements in imaging and telescopic

Fig. 4 Risk stratification of UTUC



visualization of urinary tract have helped in early and precise diagnosis and bettered follow up.

Treatment primarily based on the risk stratification of the tumor (Fig. 4). Treatment of low-risk noninvasive UTUC consists of conservative nephron-sparing surgery (e.g., endoscopic treatments, segmental resection) and adjuvant topical therapies (e.g., mitomycin-C). Depending on tumor size, number, location and access that allows complete tumor ablation, retrograde approach via ureteroscopy and ureterorenoscopy is preferred. Percutaneous antegrade approach is chosen when the location and tumor characteristics do not allow complete ablation through a retrograde approach. Radical nephroureterectomy is primary treatment option for high risk non metastatic tumor. Minimal invasive approach is preferred at least for renal part of radical nephroureterectomy as most upper tract urothelial tumors are not large or bulky. A diverse approach with various combinations of laparoscopic, open and endoscopic techniques is used for distal ureterectomy with bladder cuff excision. A cisplatin-based perioperative chemotherapy appears to have benefit in overall survival and disease-free survival has been proven by number of comprehensive studies [25]. Radiotherapy has no role as adjuvant treatment alone or as an adjunct to chemotherapy [26].

Table 1 Indication for radical nephroureterectomy [27]

Guidelines for RNU if any of the following are present:
• Suspicious imaging findings suggesting invasive UTUC
• High-grade tumor as demonstrated by urinary cytology and/or biopsy
• Multifocality with both functional kidneys
• Bulky tumors (i.e., > 2 cm)
• Variant histology

Table 2 Techniques for resection of the distal ureter and bladder cuff excision

Techniques for resection of the distal ureter and bladder cuff excision
1. Open technique
2. Transurethral resection of the ureteral orifice "pluck" technique
3. Intussusception (stripping) technique
4. Transvesical ligation and detachment technique
5. Total laparoscopic technique

6 Surgical Management

6.1 Radical Nephroureterectomy

The radical nephroureterectomy with excision of the bladder cuff is the standard treatment for UTUC (Table 1) as it fulfills all criteria for successful oncological surgery: removal of the entire tumor with an adequate margin, control of local recurrence, and control of the anatomical spread of the tumor. The intramural portion of the ureter including its orifice and a small circumferential cuff of the bladder has been mandatory because it is the part of the urinary tract at considerable risk of tumor recurrence [28]. Various techniques have been described to deal with distal ureter and bladder cuff excision (Table 2). All these techniques are equivalent for excision of the bladder cuff exception of ureteral stripping [29].

6.2 Adrenalectomy

If there is adrenal seeding or contiguous spread from a pelvic tumor, ipsilateral adrenalectomy is performed. There was no significant difference in 5-year survival, metastasis-free survival, or cancer-free survival regards to the role of adrenalectomy with localized UTUC treated by nephroureterectomy between the two groups [30].

6.3 Minimal Invasive RNU

When adhered to strict oncological principles, Laparoscopic RNU is safe in experienced hands. Multiple studies report having less blood loss, reduced postoperative pain and decreased length of stay in the laparoscopic group. However, oncological outcomes from this study show no statistically significant difference between laparoscopic and open surgery in terms of 5-year cancer-specific survival (89.9% vs. 78.8%) and 5-year metastases free survival (74.4% and 72.5%) [27, 31, 32]. Strong data is still lacking for the robotic approach, and studies are ongoing to establish its safety and benefit over the open approach [33].

6.4 Lymphadenectomy (LND)

The anatomic sites have not been clearly outlined for lymphatic drainage of the upper tract. The utilization of an LND template is probably going to own a larger impact on patient survival than the number of removed lymph nodes [34]. Lymph node positivity is reported in just 2.2% of T1 vs. 16% of pT2–4 tumors, and hence, lymphadenectomy benefited only high-grade, high-stage diseases [35]. A higher T stage increases in the likelihood of lymph node-positive disease [36]. An anatomical template-based approach should always be considered for dissection as it improves oncological outcomes [37].

6.5 Adjuvant Bladder Instillation

There is a 22–47% bladder recurrence rate after RNU for UTUC. One postoperative dose of intravesical therapy (mitomycin-C) shortly after surgery (< 72 h) proven by a meta-analysis and prospective randomized trials [38] have shown that reduces the chance of bladder tumor recurrence [39].

6.6 Conservative Surgery

The conservative treatment for UTUC includes various segmental resections or ablation via open, minimal invasive (laparoscopic, robotic or endoscopic) techniques (Table 3).

The conservative management of UTUC is as follows:

- Ureteroscopic management.
- Percutaneous approach.
- Ureteroureterostomy with adequate margins indicated for:
  - Ta low-grade tumors of the upper two-thirds of the ureter if not feasible for removal by endoscopic means.
  - In high-grade or high T stage tumors when renal preservation is a goal.
- Tumors in the distal ureter preclude its removal by endoscopic, distal ureterectomy and ureteric reimplant is performed [27].

Table 3 Recommendations for conservative management of UTUC

Recommendations for conservative management of UTUC
• Unifocal tumor
• Tumor size less than 2 cm
• Cytology or biopsy proven low grade
• Noninfiltrative lesion on CTU
• Patient understanding of close follow-up
• Inadequate renal reserve (chronic renal impairment or solitary kidney)
• Risk of bilateral disease (e.g., genetic, Balkan nephropathy)
• Significant comorbidity
• Palliation

6.7 Ureteroscopic Management (Table 4)

Ureteroscopy (URS) serves not only as a diagnostic modality but also for therapeutic purposes. For tumors in the upper ureter or in the renal pelvis which are difficult to access, a flexible ureteroscope which has a deflection angle of up to 270 ° can be used. Holmium or neodymium: yttrium–aluminum–garnet lasers are most frequently used for tumor ablation.

The grade of the disease is an important factor for successful ureteroscopic outcomes. In a study, the 5-year disease-specific survival (DSS) was 100% for Grade 1 tumors, 62.5% for Grade 2 disease and 55.6% for Grade 3 [41]. The DSS is similar for endoscopic and laparoscopic nephroureterectomy for low-Grade disease.

6.8 Percutaneous Management (Table 5)

Tumors difficult to access or when complete ablation is not achievable via retrograde approach like bulky tumor in the pelvis or upper ureter, direct access to the collecting system via percutaneous access is preferred. This is also the preferred approach in patients with suspected upper tract recurrence with a background of cystectomy with diversion for bladder carcinoma [42].

The outcomes antegrade are similar to retrograde treatment although invasive. With technological development and advances in flexible ureteroscopes with increased deflection, percutaneous methods are being used less.

Table 4 Ureteroscopic management [40]

Advantages of the ureteroscopic approach include:
• Preservation of renal function
• Reduced morbidity
• Shorter hospital stay
• Avoiding overtreatment for low-grade noninvasive disease
Disadvantages of the ureteroscopic approach include:
• Inability to treat larger tumors in one session
• Difficulty accessing upper ureteric or lower calyx tumors
• Understaging tumors
Risks of ureteroscopic treatment include:
• Ureteric perforation or avulsion causing extraluminal tumor spillage
• Ureteric strictures
• Residual disease
• Subsequent tumor upstaging and progression requiring RNU

Table 5 Percutaneous management [42]

Advantages of the percutaneous approach include:
• Better visualization
• Access to any location in the collecting system
• Treatment of large tumors in one session
• Deeper biopsies for accurate staging
• Adjuvant treatment can be administered through the nephrostomy tube left in the collecting system at the end of the procedure
• The same tract can be used for repeated procedures
Complications and risks of the percutaneous approach include:
• Bleeding requiring blood transfusions
• Obstruction of the pelviureteric junction from stricture
• Surrounding organ and pleural injury
• Risk of tumor cell seeding along the tract due to the disruption of the collecting system to gain entry

6.9 Adjuvant Therapy Following Endoscopic Treatment

To prevent disease recurrence and progression in patients with superficial bladder urothelial carcinoma, intravesical Mitomycin-C (MMC) and Bacillus Calmette-Guerin (BCG) is administered. There is limited evidence supporting the use of these adjuncts and the lack of randomized controlled trials, even though we may believe to have similar outcomes in the context of UTUC [42, 43].

These agents (MMC and BCG) can be delivered percutaneously through a nephrostomy tube, via a ureteric catheter following ureteroscopic tumor ablation retrogradely, or can be instilled in the bladder as it might reflux up via indwelling ureteric stent. There are no clear guidelines at present regarding the frequency, dosage and time of instillation of these agents in the management of UTUCs.

7 Medical Management

7.1 Neoadjuvant Chemotherapy (Table 6)

There are 60–75% pathological downstaging rates in some phase 2 trials assessing the role of neoadjuvant chemotherapeutic regimens in high-grade UTUC [46]. The patients receiving neoadjuvant chemotherapy had significantly longer 5-year overall survival (44% vs. 29%) compared who had surgery alone, with an adjusted hazard ratio (HR) of 0.47 (95% CI 0.22 to 0.99, $p = 0.047$) in a recent retrospective study [44].

7.2 Adjuvant Chemotherapy (Table 7)

There is evidence supporting adjuvant chemotherapy showing an advantage in overall survival with an HR of 0.43 (95% CI 0.21 to 0.89, $p = 0.023$) and disease-free survival with an HR of 0.49 (95% CI 0.24 to 0.99, $p = 0.048$) which comes from a meta-analysis of nine retrospective cohort studies [25]. The regimen of choice should be cisplatin based for adjuvant chemotherapy for patients with UTUC. A multi-institutional study showed favorable recurrence-free survival rates in patients who received adjuvant methotrexate, vinblastine, doxorubicin and cisplatin compared with those who received gemcitabine and cisplatin (71.4% vs. 48.2%, $p = 0.022$) [47].

A randomized POUT trial in UTUC has shown a benefit of using adjuvant chemotherapy in pT2–pT4 or LN-positive patients. Adjuvant chemotherapy has improved disease free survival and is better tolerated. As efficacy was favoring the chemotherapy arm, the recruitments in the trial were terminated early [48].

Table 6 Neoadjuvant chemotherapy [44]

Rationale of neoadjuvant chemotherapy
1. Able to tolerate chemotherapy with two functioning kidneys prior to RNU
2. Pathological downstaging gives clinicians important prognostication information
3. Level I evidence from urothelial carcinoma of the bladder recommending neoadjuvant chemotherapy prior to radical cystectomy [45]
Disadvantages of neoadjuvant chemotherapy
1. A delay to definitive surgical management, particularly in chemo resistant disease
2. Increase in perioperative morbidity
3. Overtreatment in patients who may simply have low-risk disease

Table 7 Adjuvant chemotherapy [25]

Advantages of adjuvant chemotherapy include:
• The availability of accurate postoperative pathological staging in order not to overtreat noninvasive disease
• Eradication of any subclinical micro metastases in order to maximize a patient's survival
Disadvantages of adjuvant chemotherapy include:
• Subjecting patients to potentially nephrotoxic chemotherapy after removal of one kidney

8 Radiation Management

The rationale for adjuvant radiation therapy (RT) is to decrease the risk of local recurrence after radical surgery for locally advanced disease (stage T3 to T4, N+). Because of a paucity of data, the role of radiation in the adjuvant management of UTUC is poorly clarified. A 3-year local recurrence-free survival rates were 89% vs. 61% in the RT vs. non radiation groups ($P = 0.01$) in patients with stage III/IV UTUC [49]. Fan et al. demonstrated improved overall survival for patients receiving adjuvant chemoradiation following surgery vs. chemotherapy and salvage radiation therapy [50]. However, another study reported no additional survival benefit compared to standard surgical therapy, as 5-year overall survival rates and recurrence-free survival rates were 49% and 30%, respectively, proving that RNU alone provides a high local control [51]. Also, for high-stage disease, adjuvant radiation without chemotherapy does not preclude chances of metastasis. The present data supporting is retrospective and small; however, there is a role for combined chemo-radiation in patients with advanced disease with adverse features.

11 Management of Recurrent Disease Including Specific Palliative Measures

The RNU alone is offered only in the palliative circumstance in patients with metastatic UTUC as there is no oncological advantage [53]. In selected metastatic UTUC patients who are fit to receive treatment, there is an overall survival advantage in combining chemotherapy and RNU vs. chemotherapy alone [54]. Recent trials of new immunotherapeutic drugs (PD1 inhibitors) have demonstrated a response in a proportion of patients with UTUCs; hence, they can be used for second-line treatment in metastatic UTUC; however, it still remains a challenge [55].

12 How We Do It at TMC

- Patients are referred to TMC for UTUC cancer based on radiological or endoscopic findings of mass in the upper tract.
- Based on available imaging, urine cytology is sent for all patients.
- Radiological evidence and cytology positivity are sufficient to prove the diagnosis of tumor.
- Biopsy (endoscopic/image-guided) is advised when radiological/cytological evidence is insufficient to prove the diagnosis.
- Histopathology reported elsewhere is reviewed by GU pathologist at TMC to confirm concordance of grade, depth and ruling out variant histology.
- Cystoscopic evaluation is done in all patients to rule synchronous bladder tumor.
- UTUC patients are categorized into low or high risk based on risk stratification suggested by the EAU guidelines.
- All low-risk tumors are managed conservatively.
- Radical nephroureterectomy with bladder cuff excision with template lymphadenectomy is the treatment of choice for all high-risk patients except when preservation of renal function is a goal. It is performed either open or minimally invasive technique (laparoscopic/robotic).
- Perioperative single intravesical instillation of Mitomycin-C is done in all patients undergoing radical nephroureterectomy.
- Adjuvant treatment is considered in high-grade and high-risk patients.
- Surveillance of all patients is done as per EAU guidelines.
- Patients with metastatic disease are considered for palliative chemotherapy, pain management, nephrostomy, angioembolization and palliative radiotherapy based on their presentation and performance status.

VMAT	Volumetric-modulated arc therapy
WW	Watchful waiting

1 Epidemiology

- Second most common malignancy in men after lung cancer.
- Incidence variable across countries due to differences in implementation of screening.
- Higher prevalence in the West.
- GLOBOCAN 2018 data [1]: 7.1% of all new cancers worldwide (1.3 million cases) and 3.8% of all cancer related deaths (359,000 deaths).
- The age-adjusted deaths from prostate cancer have declined 51% from 1993 to 2014 [2].
- The decreasing and comparatively low death rate may be a result of increased public awareness leading to early detection and treatment.
- Both environmental and genetic factors play a role in pathogenesis.
- Age, race and family history are important risk factors.
- Risk of prostate cancer in first-degree relatives is twofold higher than general population.
- Additionally, if prostate cancer is diagnosed in men <60 years of age, this risk increases by fourfold.
- Genomic studies have reported 77 SNPs associated with prostate cancer [3].
- BRCA 2 mutations are important mutations increasing risk by 5- to sevenfold.
- Other mutations/genes implicated are CHEK2, PALB2, BRIP1 and NBS1.
- Molecular classification emerging to streamline treatment guidelines.

2 Clinical Features [2, 4]

The clinical manifestations of prostate cancer often mimic those of benign prostatic hypertrophy/hyperplasia (BPH) which is more common than prostatic cancer. Both conditions often coexist in elderly males. Careful history and physical examination can provide clues towards making a correct diagnosis in most cases.

2.1 Symptoms

In the West, most patients are asymptomatic and report to their heath caregivers with raised or abnormal PSA levels. However, in developing countries including India, symptoms of metastatic disease, bladder outlet obstruction and haematuria are common presentations.

The symptomatology of prostate cancer can be divided as:

1. *Asymptomatic*: Most men with early stage prostate cancer may have no symptoms attributable to the cancer.
2. *Local symptoms*: Include *low back ache, lower urinary tract symptoms (LUTS)* due to an enlarged prostate, *erectile dysfunction, hematuria* and *hematospermia*. An overlapping problem of coexisting urinary tract irritation/infection can mislead the clinician. Symptoms of urinary frequency, urgency, nocturia and hesitancy are often related to a concomitant BPH. Hematuria and hematospermia though uncommon, their presence in older men should raise the suspicion of prostate cancer. Erectile dysfunction is considered to be a late symptom and is due to invasion of the neurovascular bundles.
3. *Symptoms due to metastases*: *Bone pain* due to bony metastases is the commonest symptom. Others include *cough, breathlessness, haemoptysis* and *abdominal pain* due to hepatomegaly. Occasional patients can also present with *palpable masses, lymphedema* or *venous thromboembolism* secondary to nodal enlargement.
4. *Acute symptoms: Acute urinary retention, massive haematuria* or *pathological fractures* including *spinal cord compression and symptoms related to hypercalcaemia* can be found.

2.2 Clinical Examination

General physical examination may reveal *pallor, supraclavicular adenopathy, hepatomegaly, ascites* and *pedal oedema.*

Digital rectal examination (DRE): Presence of asymmetric areas of induration or nodules suggests cancer. Patients with an abnormal DRE irrespective of serum PSA levels warrant further evaluation in the form of prostatic biopsy. DRE detects tumours in the posterior and lateral aspects of the gland. However, tumours in other parts or small tumours may be missed on DRE. The PPV for malignancy with an abnormal DRE is around 12%.

3 Evaluation of Prostate Cancer [5]

The evaluation of prostate cancer complements a good history taking and physical examination with special emphasis on digital rectal examination for prostate assessment.

3.1 Serum PSA

- Serine protease (glycoprotein) secreted by prostatic epithelium.
- Produced by the action of Human Kallikrein-2 enzyme on the precursor ProPSA.
- Normally present in semen and serves to cleave and liquefy seminal coagulum.
- Normal value: <4 ng/mL with $t^{1/2}$ of 2.2 days.
- Two forms: Free PSA and bound PSA (alpha 1-antichymotrypsin (90%)/alpha 2-macroglobulin).
- Increase in PSA: Due to disruption of cellular architecture within prostate; seen in prostate cancer, prostatitis, BPH, following prostate biopsy, prostatic infarction, recent sexual activity, following TURP (PSA is thus organ but not cancer specific).
- Decrease in PSA: following hormonal therapy.
- A value of >10 ng/mL has a 67% probability of cancer. Thirty percent of men with high PSA will have prostate cancer. PPV of PSA is 25–40%. Generally, patients with prostate cancer will have values >20 ng/mL.
- Uses: Detection of primary/recurrent tumours; during follow-up; tool for screening along with DRE.
- Types
  - (a) *PSA density*: Defined as serum PSA/volume of prostate gland. Normal value is <0.15. It has a sensitivity of 75% and specificity of 44% in diagnosis.
  - (b) *PSA velocity*: Defined as rate of change of PSA. An increase of 0.75 ng/mL/year increases cancer risk. Rapid PSA doubling is associated with increased treatment failure rates and increase in cancer related mortality.
  - (c) *Complexed PSA*: Defined as ratio of free PSA/total PSA.
  - (d) *PSA density of transitional zone*: Defined as ratio of serum PSA to volume of transitional zone.
  - (e) *% Free PSA*: Defined as free PSA/total PSA X 100. A lower value (<10%) indicates cancer while a value >25% implies no risk. It is valuable when serum PSA is 4–10 ng/mL (borderline) and there is history of previous negative biopsy.

3.2 TRUS

- One of the most accurate method for local staging in prostate cancer.
- Besides obtaining biopsy, it is also used for screening, for measurement of prostate volume, to assess prostate blood flow and in brachytherapy/cryotherapy of gland.
- Probe frequency is 7 MHz.
- Prostate cancers appear as hypoechoic nodules (60–70% cases). Extra-capsular spread is suggested by identifying a bulge in the prostate contour and an angulated appearance of lateral margin. Seminal vesicle involvement is denoted by bulge at the base of the seminal vesicle and altered echogenicity.
- D/Ds of hypoechoic nodules include infarcts, granulomas and lymphomas.
- Advantages: Cost effective, no risk of radiation and day care procedure.

3.3 Prostate Biopsy

- Indications: a) Palpable masses on DRE (abnormal DRE); b) elevated PSA; c) both elevated PSA with abnormal DRE.
- Types: (a) *Sextent* (6 cores): Higher false negativity of 15–34%; (b) *extended* (10–12 cores): Increases detection rate and current gold standard; (c) *saturation* (18–21 cores): Increases detection rate and also detection of insignificant (low grade) prostate cancers. It is used when primary biopsy is negative and involves biopsy of the prostatic apex.
- Methods: a) *TRUS guided;* b) *transperineal*: A reduction in risk of sepsis (<1%) but an increase in urinary retention (2%–9%); c) m,*ultiparametric MRI guided*: Useful for patients undergoing repeat biopsy (increases detection in up to 54% cases) and improves sampling rates and d) *MRI/TRUS fusion biopsy.*
- Gun used: *End fire sampling* tend to have better detection rates compared to *Side fire sampling* in retrospective studies. However, RCTs show no difference.
- Complications: (a) Bleeding (1%–4%); (b) infections (0.1%–7%); (c) UTI (2%–6%); (d) urinary retention (1%) and (e) vasovagal attack (1.4%–5.3%).
- Implications:
  - HGPIN on biopsy: No immediate treatment needed; repeat biopsy after 3 years.
  - Multifocal HGPIN: Doubles risk of cancer; repeat biopsy within first year.
  - Adenocarcinoma: Stage and treat accordingly based on Gleason score, PSA.
- Repeat biopsy: Performed when a) raising PSA with initial negative biopsy; b) persistently elevated PSA; c) abnormal histologies like ASAP; d) % free PSA < 10% and e) inadequate initial biopsy. A repeat biopsy increases cancer detection by 16%–40%.
- Gleason score: Most common system used for grading prostate cancer. It is based on glandular pattern at low magnification and degree of glandular differentiation. Grading occurs from 1 to 5 where 1 indicates well differentiation and 5 poorly differentiated cancers. Based on the grade, a Gleason score (GS) is calculated using the dominant grade identified + next dominant grade present. Therefore, GS varies from 2 to 10. A tertiary GS is one in which a high-grade minor component is also added to the score. Poorly differentiated tumours have a GS: 8–10 while well-differentiated tumours have a GS: 2–4.

3.4 PSMA PETCT

- Staging modality for prostate cancer especially for intermediate and high-risk prostate cancers by offering ‘one stop shop’ for staging by demonstrating local infiltration, lymphatic spread and distant metastases.
- PSMA: Prostate-specific membrane antigen is a 750 amino acid trans-membrane protein located within the apical epithelium of secretory ducts of normal prostate tissue.
- In malignancy, PSMA expression in elevated in tumour tissues compared to benign prostatic hyperplasia/enlargement which show no increased uptake. This increased expression correlates with Gleason score and PSA levels.
- Provides additional molecular information on disease distribution over and above standard imaging.
- In patients with biochemical recurrences, PSMA can help distinguish local recurrence or nodal metastases, even when PSA levels are low.
- PSMA PET is better than conventional bone scans for detecting bone metastases.
- *Theranostic application* by linking PSMA antibodies to radio-ligands to facilitate elective irradiation.
- Overall sensitivity is fairly moderate (33%–66%) but specificity is excellent (98%–100%).
- PSMA is not prostate specific: Physiological uptake occurs in kidney, salivary glands, small bowel, spleen and liver. It can also be expressed by other tumours like gastric, colorectal, breast and renal cancers.
- Recent meta-analysis of 1309 patients evaluated in16 studies failed to make any form of conclusive recommendations for use in staging [6].
- PSMA negative prostate cancers, micrometastases are common causes of false-negative results.
- Ubiquitous availability of these scans is still a realization.

3.5 FDG PETCT

- As an alternative for staging when PSMA PETCT scans not available.
- FDG uptake correlates with more aggressive tumours with poorly differentiated histologies.
- May be less sensitive for detection of bony metastases as PETCT picks up lytic lesions better than sclerotic lesions.
- Lower sensitivity compared to PSMA PETCT.

3.6 Tc^{99}Bone Scan

- Tc^{99}-MDP (Technetium methylene diphosphonate) bone scan is still the standard of care for evaluation of bony metastases.
- Usually indicated when PSA > 20 ng/mL, presence of bony symptoms or locally advanced disease (cT3/T4).
- Increased uptake correlates with osteoblastic activity: Feature of prostate cancer metastases (>80%).
- Higher false positives: Degenerative bony diseases, inflammation and fracture sites.

3.7 MRI Pelvis

- Prostate cancer appears as reduced signal intensity in the peripheral zone on T2W images.
- Improves local staging by depicting adjacent soft tissue involvement.
- Accuracy of staging varies from 51% to 92%.
- Relatively expensive, operator dependent and difficult to perform biopsies.
- Multiparametric MRI: Combines T2W imaging with diffusion weighted imaging and MR spectroscopy. It helps increasing detection rates.

3.8 CT Scan

- Features of malignancy include obliteration of periprostatic fat planes, abnormal enhancement of contiguous NVB and extension into adjacent organs.
- Demonstrates bladder/rectal invasion, lymphadenopathy and distant metastases.
- Can be used to obtain FNAC from lymph nodes increasing accuracy.

3.9 Blood Investigations

- Complete hemogram: May demonstrate a) anaemia due to chronic hematuria/secondary to renal failure/leucoerythroblastic anaemia; b) leukopenia due to leucoerythroblastic anaemia and c) thrombocytopenia due to DIC/bone marrow invasion.
- Liver function tests: May be abnormal due to extensive liver infiltration.
- Renal function tests: May show azotaemia due to bilateral ureteric obstruction secondary to trigonal involvement or due to extensive retroperitoneal nodes causing ureteric compression.

3.10 Prostascint

- Form of radio immunoscintigraphy: Murine monoclonal antibody to the intracellular component of PSMA conjugated with Indium (In^{111}) is infused into patients. SPECT images are then taken to depict uptake at various sites.
- Relatively expensive and cumbersome and not routinely used.

4 Screening

- Important because most prostate cancers are indolent in nature; as a result, the majority of patients die with prostate cancer rather than from it.
- Important because treatment-related morbidity and side effects impair the quality of life of these patients in the long run.
- Therefore, a screening program which can accurately pick up asymptomatic men with aggressive localized tumours which can contribute to prostate cancer-related mortality and be diagnosed early and treated.
- PSA has been used as a marker for screening.
- The European Randomized Study of Screening for Prostate Cancer (ERSPC) Trial [7] reported an absolute survival benefit (albeit small) with PSA screening at 9 years of follow-up.
- The Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial [8] found no benefit with combined annual PSA and digital rectal examination screening after 7–10 years of follow-up.
- Conflicting trial results have made screening in prostate cancer a controversial topic.
- Although screening with PSA can reduce cancer-specific mortality, the absolute risk reduction is small.
- The benefits of screening being outweighed by the potential harms including the substantial risk of over-diagnosis need to be kept in mind before undertaking screening.
- In India, opportunistic screening in which PSA is undertaken in patients who visit the health care provider is followed.

- Thorough discussion with the patient important in this regard before initiation of screening.
- US Preventive Task Force (USPTF) 2017 guidelines [9]: For men above 70 years, no PSA-based screening is recommended (category D) and for men between the ages of 55–69 years, PSA-based screening must be individualized (Category C recommendation).

5 Principles of Treatment

5.1 Localized Prostate Cancer

- Disease confined within the gland with no extra prostatic extension or distant metastases which includes T1-T2c, N0 and M0 cancers.
- Treated with curative intent.
- T1 cancers: Diagnosed incidentally on TURP specimens undertaken for coexisting BPH.
- Patient with good PS and life expectancy of >/= 10 years, radical prostatectomy remains the treatment of choice.
- Patient is unfit or is unwilling for surgery, radical radiotherapy is used.
- Active surveillance is an option in patients who are compliant for follow-up and have cancers fitting into the Epstein criteria (very low risk tumours) with a life expectancy of 10 years or more.

5.2 Locally Advanced Prostate Cancer

- Cancer outside the prostate gland but confined to the pelvis with no distant metastases.
- Includes T3-T4a, N0-N1 tumours.
- Multimodality treatment is necessary.
- Options include
  - RP followed by RT + HT.
  - NAHT followed by RT + HT.
- Neoadjuvant hormonal therapy reduces the tumour burden and helps achieve negative margins, given for 6 months prior to definitive treatment and continued for 2–3 years.
- Nodal disease must be addressed appropriately.
- Active surveillance is not an option in these patients.

5.3 Metastatic Prostate Cancer

- Includes cancers with distant nodal and/or visceral metastases.
- The performance status of patient, life expectancy, site and volume of disease: Important factors for consideration of treatment.
- Patients with poor PS and low life expectancy: ‘Watchful Waiting’ where symptomatic treatment is initiated only when symptoms appear.
- Combination of chemotherapy and hormonal therapy (chemo-hormonal therapy) is used.
- Chemotherapy is important in those with high volume of disease burden especially visceral metastases. Agents include docetaxel, abiraterone, etc.
- Abiraterone is used as frontline therapy for patients without visceral metastases.
- Hormonal therapy includes surgical (bilateral orchiectomy) or medical castration (GNRH analogues [agonists/antagonists] or anti-androgens).
- Surgical castration is cheaper, one-time treatment, irreversible but may have psychological effects on the patient.
- GNRH analogues are administered every 3–6 monthly lifelong. They are more expensive.
- Anti-androgens (e.g. bicalutamide) are oral formulations that are administered along with surgical castration.
- Hormonal therapy causes cardiac problems, osteoporosis with prolonged usage.

5.4 Castrate-Resistant Prostate Cancer (CRPC)

- Cancers which are not hormonally sensitive.
- Resistance occurs due to various mechanisms.
- Treatment involves use of chemotherapy, ketoconazole, immunotherapy and oestrogens.
- Associated with prostate cancer related mortality.

6 Radical Prostatectomy [4]

Radical prostatectomy is the oldest curative treatment for prostate cancer and remains a ‘gold standard’ modality because:

- Hormonal or chemotherapy are never curative,
- Radiotherapy or other physical forms of energy may not completely eradicate all cancer cells, even in a gland contained cancer.

6.1 Indications

- Patients with cT2 or lower cancers.
- High risk localized prostate cancer defined by PSA>/= 20 OR Gleason score >/= 8 OR clinical stage T of >/= 3a.

Patients must have a life expectancy of at least 10 years. The tumour should be biologically significant and completely resectable. The accepted upper age limit to undertake the surgery is about 75 years.

6.2 Methods/Types

6.2.1 Open Radical Prostatectomy

- e. Retropubic prostatectomy: This technique was first propounded by Millin in 1947. Generally, this approach is adopted due to familiar surgical anatomy; lower risk of rectal injury and postoperative faecal incontinence, wider exposure and access for performing pelvic lymphadenectomy, preservation of the neurovascular bundles and lesser risk of positive margins. However, it is associated with increased blood loss, impotence and urinary incontinence.
- Perineal prostatectomy: Associated with less blood loss and shorter operative time than the retropubic approach. The potential disadvantages are poor access for performing a pelvic lymphadenectomy, higher rate of rectal injuries and occasional postoperative faecal incontinence. It is also more difficult to preserve the cavernosal nerves with this approach.

6.2.2 Laparoscopic Radical Prostatectomy

It is associated with less bleeding and post-operative pain, better visualization and shorter recovery time. Performed through transperitoneal or extraperitoneal approaches. Transperitoneal approach facilitates lymphadenectomy but has a higher risk of adjacent intestinal and vascular injury, urinary leaks and postoperative bowel obstruction. Haemostasis in the neurovascular bundles is difficult due the relative difficulty in the placement of haemostatic sutures/clips. Additionally, heat from the cautery can irreversibly damage them. The rates of positive margins have been reported higher and oncological adequacy remains to be proven.

6.2.3 Robotic/Robotic-Assisted Radical Prostatectomy

Associated with greater technical ease, especially for suturing the vesico-urethral anastomosis. It is less invasive and associated with lower pain and a quicker recovery. Cost can be a deterrent for usage. The only phase III randomized trial comparing robotic with open prostatectomy was conducted in Australia and found no difference in oncological and functional outcome of the two techniques at a follow-up of 24 months [10]. A recent Cochrane review that compared either robotic radical prostatectomy (RARP) or laparoscopic RP (LRP) vs. open radical prostatectomy (ORP) included two RCTs. The main conclusions were that there were no significant differences between the comparisons for oncological, urinary function and sexual function outcomes, although the minimally invasive techniques were associated with a statistically significant improvement in duration of hospital stay and blood transfusion rates over open RP. Thus, there is no recommendation of surgical approach of one over the other [11].

6.2.4 Salvage Prostatectomy

Performed in patients where local treatments have failed. It is associated with higher and more serious complications that are much more difficult to manage.

6.3 Main Steps of Prostatectomy

- Opening of the endopelvic fascia and limited incision of the puboprostatic ligaments.
- Suture ligation and transection of Santorini’s dorsal venous complex.
- Dissection of urethra at the prostatic apex and urethral transection.
- Dissection of the prostate from the neurovascular bundles.
- Transection of the prostatic pedicles.
- Transection and reconstruction of the neck of the bladder.
- Dissection of seminal vesicles and vas deferens.
- Performance of vesicourethral anastomosis.
- Pelvic lymphadenectomy.

6.4 Post-Operative Care

- Catheter removal 3 to 21 days after surgery. Removal of the catheter before 7 days is associated with a 15% to 20% risk of urinary retention.
- Kegel’s exercises.
- Protective pads or diapers may be used until complete urinary control is achieved.
- Postoperative serum PSA levels should be undetectable by 30 days after surgery.

6.5 Complications

- *Early*: Haemorrhage; adjacent structure (rectal, vascular, ureteral or nerve) injuries; urinary leak/fistula formation; thromboembolic and cardiovascular events; urinary tract infection; lymphocoele and wound infection.
- *Late*: Erectile dysfunction, urinary incontinence and urethral strictures.

6.6 Contraindications

Mainly for minimally invasive techniques and include:

- *Absolute*: Uncorrectable coagulopathies, inability to undergo general anaesthesia.
- *Relative*: Prior lower abdominal/pelvic surgery, morbid obesity, large prostate size (e.g. >100 g), prior pelvic irradiation or prior prostate surgery.

6.7 Adjuvant Therapy after Surgery

- *Node negative*: Adjuvant radiotherapy for pT3 tumours and margin positivity. However, survival advantage may not be significantly different compared to salvage radiotherapy at biochemical recurrence.
- *Node positive*: Androgen-deprivation therapy (ADT), either immediate or delayed, leads to improvement in disease free and overall survival. Use of adjuvant radiotherapy remains controversial.

6.8 Evidence

- Scandinavian trial [12]: At a median follow-up of 13 years, patients who underwent radical prostatectomy had a reduction in cancer-related mortality (RR: 0.56 and absolute risk difference of 11%) compared to those undergoing watchful waiting in the study that included 695 men.
- PIVOT (Prostate Cancer Intervention Versus Observation Trial) [13]: Showed survival benefit in those with high-risk features (e.g. PSA>/= 10) on subset analysis.
- SWOG 8794 trial [14]: Adjuvant RT improved OS and metastases-free survival in patients with margin positive or pT3 disease.
- EORTC 22911 trial [15]: Improved biochemical-free survival and reduction in local recurrence in patients >70 years old or those with positive margins.

6.9 Advantages

- Possibility of cure with minimal surgical trauma to surrounding tissues.
- Accurate tumour staging for planning further treatment.
- Treatment failure easily identified by PSA estimation during follow-up.
- Relatively smooth postoperative course, short hospital stay and very low post-operative mortality.
- Reduction in disease progression locally as well as reduction in the risk of distant metastases, thus improving cancer-specific and overall survival.
- Recurrences can be salvaged by radiotherapy.

6.10 Disadvantages

- Possibility of incomplete resection of the tumour.
- Risk of erectile dysfunction and urinary incontinence are comparatively lesser with use of nerve sparing techniques.

7 Active Surveillance (as) [16]

7.1 Definition

This includes observation rather than immediate therapy, with curative intent treatment deferred until there is evidence that such patients are at increased risk of disease progression.

7.2 Rationale

- Carcinoma prostate is often detected when it is not clinically evident.
- Indolent cancers can often be differentiated from aggressive ones by clinico-pathological parameters.
- Any form of definitive treatment is always associated with appreciable side effects and costs.
- By adopting surveillance, those patients who are at high risk of disease progression receive definitive therapy.
- Thereby, quality of life remains unaffected in majority of patients which becomes an important parameter in younger patients with respect to voiding and sexual disturbances.

7.3 Indications

AS is applicable to most men with Gleason 6 cancer; also, selected patients with Gleason score (GS): 3 + 4 with a low percentage of component 4 may be candidates for active surveillance. Patients with a life expectancy of >10 years are offered AS. There is no lower age limit for AS.

7.4 Components of AS

7.4.1 Selection of Patients Who Are at Low Risk of Disease Progression

- Many clinico-pathological criteria exist to select these patients.
- These criteria include early clinical stages, low PSA levels and a GS consistent with a well-differentiated cancer.

Some of them also include number of positive biopsy cores and percentage of positive cores, PSA density and PSA kinetics to select patients.
- Endo-rectal MRI can often be used as a complementary tool to improve patient selection by increasing the accuracy and yield of prostatic biopsies. MRI has a 93% sensitivity in this regard.
- All patients must be adequately counselled regarding the treatment strategy and need to adhere for stringent follow-up.

7.4.2 Surveillance Strategy

- Patients are followed with serial PSA and repeat biopsies.
- Initial confirmatory biopsy is performed at 6–12 months, mainly targeting those prostatic zones that may be underevaluated during initial biopsy. Twenty-five to 3 percent of these patients may have a higher tumour grade which could have been missed during the initial biopsy. The basic premise of this confirmatory biopsy is to evaluate presence of higher grade tumour which makes patients unsuitable for active surveillance.
- A routine strategy includes half-yearly PSA, yearly DRE and a repeat biopsy with or without imaging at 3–5-year intervals.
- The interval between tests depends on patient's underlying risk factors and concern/anxiety regarding cancer spread.
- Five alpha reductase inhibitors (e.g. dutasteride) are being used to prevent or delay disease progression in patients managed under active surveillance.

7.4.3 Criteria for Switching from AS to Definitive Treatment

- When repeat biopsy shows Gleason 4/5.
- Increase in either the number of positive cores or percentage of positive cores on biopsy.

7.5 Guidelines

The guidelines from important associations have been listed in Table 1.

7.6 Outcomes

- PIVOT trial [13]: Lack of survival benefit of immediate surgery compared to observation alone at 12 years.
- ProtecT trial [20]: Compared AS with radical prostatectomy and radical radiotherapy for localized prostate cancer. This included 82,429 men and the primary end point was prostate cancer specific mortality at 10 years. This trial showed no difference is mortality among the 3 arms. However, both the surgery and radiotherapy arms were associated with lower disease progression and development of metastatic disease.

7.7 Advantages

- About two-thirds of early stage cancer patients will avoid treatment.
- Side effects of treatment is reduced.
- Quality of life remains unaffected.
- Reduces the need for treating small, indolent cancers.

7.8 Disadvantages

- Can lead to psychological harm and unfound anxiety in patients.
- Increased risk of erectile dysfunction in those undergoing repeat biopsies.
- About one-third of patients will eventually require treatment, although there may be no impact on cure rates.

Table 1 Guidelines for active surveillance from various international associations

Guidelines	Low risk	Intermediate risk	Tests	Other tests
ASCO[17] (2016)	AS preferred	Active treatment; AS for selected patients	PSA q3–6 months DRE q1 year Biopsy: within 6–12 months, then q3–5 yearly	MRI investigational
AUA[18] (2017)	Same	AS for selected patients	Same	Same
NICE[19] (2016)	Same	Radical treatment	PSA q3–4 months, monitor kinetics; rest same	MRI at enrolment

ASCO American Society of Clinical Oncology, *AUA* American Urological Association, *NICE* National Institute for Health and Care Excellence, *AS* active surveillance, *DRE* digital rectal examination

Table 2 Important trials for active surveillance in prostate cancer

Study	n	Follow-up (median) (in years)	Freedom from treatment	No biochemical evidence of disease	Prostate cancer mortality	OS
UCSF [21]	321	3.6	67%@5 years	1 recurrence at 3 years	0	0
University Toronto [22]	993	8.5	70%@5 years	47%: at 5 years	5% @ 15 years	10 year OS: 68%
PRIAS [23]	2494	1.6	77% @2 years	–	0	4 year OS: 87%
University of Miami [24]	230	2.6	85.7% @ 5 years	0	0	–
John Hopkins [25]	1298	5	59% @ 5 years	90.6% at 2 years	0.1% at 15 years	15 year OS: 69%
Royal Marsden [26]	471	5.7	70% @ 5 years	85% at 5 years	2% at 8 years	8 year OS: 9%

OS overall survival, *UCSF* University of California, San Francisco, *PRIAS* Prostate Cancer Research International Active Surveillance

7.9 Evidence

Nine prospective studies which include around 10,000 men have been published. The largest and most mature data is shown in Table 2.

The limitation of most of these studies is that the follow-up period is relatively small.

An important term to be differentiated is ‘watchful waiting’ (WW). In WW, monitoring continues until patient develops symptoms when palliative androgen-deprivation therapy is instituted. This method is adopted for patients who have a life expectancy of less than 10 years. This could be applied to all prostate cancer patients irrespective of cancer stage.

8 Focal Ablation [27, 28]

Focal ablation is a form of local therapy to treat localized prostate cancer.

8.1 Rationale

The lesion with the largest and highest grade (in the setting of multifocal disease) serves as the driver for clinical progression of disease. By ablating this index lesion, disease progression can be delayed or stopped. Use of multiparametric MRI can confidently target suspicious lesions for biopsy and hence ablation.

8.2 Indications

Indicated for small (at least 0.5 m^3 with a maximum core length of >/= 6 mm of cancerous tissue) or any sized lesion with Gleason 4 or more.

8.3 Contraindications

- Those with contraindications to MRI (pacemaker, aneurysmal clips, etc.)
- Allergic to MRI contrast.
- Significant CKD precluding contrast use.
- Those with clinically insignificant disease of size less than 0.5 mm^3 or low Gleason score (</= 3).

8.4 Methods

Ablation can be performed by various techniques that include high-frequency ultrasound (HIFU), cryoablation, laser ablation, photodynamic therapy, focal brachytherapy, radiofrequency ablation (RFA) and irreversible electroporation. Candidates are selected using template mapping or multiparametric MRI-based biopsies to appropriately identify these lesions. Treatment techniques include targeted focal ablation, hemiablation and hockey stick patterns (anterior and posterior). Lesions which are not clinically significant must not be targeted.

8.5 Follow-Up and Outcome Assessment

- Disease recurrence is assessed using biopsies which are performed in view of raising PSA, suspicious MRI or both.
- Biopsy must be 4–6 targeted cores from margins of zone of ablation which included at least 1 sample from ablated zone.
- Follow-up MRI must be done 6–12 months after procedure to identify failure or recurrence.
- Treatment may include reablation, active surveillance of whole gland therapy.

8.6 Advantages

- Offers good oncological outcomes with low complication rates.
- Healthy gland is preserved and minimizes risk of damage to adjacent structures.
- Performed as a day care procedure.

9 Radiotherapy

For men with localized prostate cancer, external beam radiation therapy (EBRT) along with androgen-deprivation therapy (ADT) has become the standard definitive treatment option for with long-term control outcomes comparable to surgery [21]. Improvements using cross-sectional imaging for treatment planning [29] and intensity-modulated radiotherapy [30] with daily image guidance [31] have permitted accurate delivery of radiation to the target.

The sensitivity to fractionation of irradiated tissue is characterized by a parameter called the α/β ratio. The α/β ratio of adenocarcinoma prostate is low, in the range of 1–2Gy [32–34]. The α/β ratio of the adjacent rectum is greater than that of prostate cancer [35, 36], implying that hypofractionation may further improve the therapeutic ratio of EBRT.

9.1 Definitions

A recent publication by Morgan et al. [37] has defined the following schedules.

Type	Fraction size (Gy)
Conventional	1.8–2
Moderate hypofractionation	2.4–3.4
Ultra-hypofractionation	≥ 5

The fraction size gap created by definitions (3.4-5Gy) represents a relatively little studied range.

9.2 EBRT Techniques

The prostate, rectum and bladder are delineated on axial pelvic computed tomography (CT) images. Treatment planning algorithms then calculate the dose and the beam arrangements are planned to the target volume.

- Three-dimensional conformal RT (3D-CRT).
- Intensity-modulated RT (IMRT)—Delivers non-uniform beam intensities with dose escalation. Volumetric-modulated arc therapy (VMAT) is an evolution of IMRT with a circular technique of radiation delivery.
- Image-guided RT (IGRT)—Technique acquiring 2D/3D images prior to each treatment providing accurate localization of the prostate, which varies daily due to bladder and rectum filling, e.g. gold marker (fiducial) tracking with megavoltage imaging, kilo-voltage (kV) imaging, abdominal ultrasound or CBCT.
- Stereotactic body RT (SBRT)—Alternative for selected men with low to intermediate risk.
- Proton beam RT—Majority of the energy is deposited in the region of the Bragg peak, beyond which the dose sharply falls to zero.
- Carbon ion RT—Being evaluated, primarily in Japan, as an alternative form of particle irradiation.

Gold Standard for EBRT—IMRT with IGRT

9.3 Indications

- Definitive radiotherapy
- Adjuvant radiotherapy
- Salvage radiotherapy
- Hypofractionation

10 Definitive Radiotherapy

10.1 Low Risk

The ProtecT [19] trial randomized 1643 patients to active treatment (RP/EBRT) and Active Surveillance which confirmed that RT plus 6 months of ADT improved PFS but not OS. If RT is performed in this group, dose escalated IMRT (74-80Gy) alone, or moderate hypofractionation should be used. LDR brachytherapy is an alternative.

10.2 Intermediate Risk

IMRT with short-term ADT (4–6 months) can be used to treat such patients suitable for ADT [38–40]. For unsuitable patients or unwilling for ADT, the recommendation is dose escalated IMRT/VMAT with or without brachytherapy. HDR brachytherapy alone is a valid treatment option for select patients conferring 5-year PSA control >90%, with minimal (<5%) late Grade 3+ GU and GI toxicity [41, 42].

10.3 High Risk

Dose escalated IMRT/VMAT and long-term ADT is the preferred approach as per current recommendation. The role of pelvic radiation is being evaluated in recent trials.

Table 3 Trials for androgen depravation therapy with radiotherapy in locally advanced prostate cancer

Study	n	Median F/U(yr)	Randomization	Outcomes
Intergroup T94–0110[44]	1205 (1057 with T3–4 disease)	8	ADT vs. ADT + RT (65-69Gy) ADT: Lifelong LHRH agonist or bilateral orchiectomy	10 year OS: 45% vs. 55% ($I = 0.001$)
RTOG 85–31[45]	945 [T3 (82%) or N1(18%)]	7.6	RT vs. RT + ADT(44–46Gy to whole pelvis; 20–25Gy boost to prostate) ADT: Goserelin at least 2 years, preferably until progression	10 year OS: 39% vs. 49%, ($p = 0.002$) 10 year DSS: 78% vs 84%, ($p = 0.005$) OS benefit limited to patients with Gleason 7–10
EORTC 22961[46]	970 (T2c-T4 or N1–2)	6.4	RT + ADT for 6 months vs. RT + ADT for 36 months (prostate dose: 70Gy) ADT: 6 months CAB (LHRH agonist + anti-androgen) ± 2.5 years LHRH agonist	5 year OS: 81% vs. 85% ($p = 0.02$) 5 year DSS: 95% vs. 97% ($p = 0.002$)
DART 01/05 Spain [47]	355 (47% IR, 53% HR)	5.3	RT + ADT for 4 months vs. RT + ADT for 28 months (prostate dose:76–82Gy) ADT: Goserelin + anti-androgen for 4 months total (prior to andduring RT) ±2 years Goserelin	5 year OS: 86% vs. 95% ($p = 0.009$) 5 year BRFS: 81% vs. 89% ($p = 0.019$) 5 year metastasis-free survival: 83% vs. 94% ($p = 0.009$)

IR intermediate risk, *HR* high risk, *ADT* androgen deprivation therapy, *BRFS* biochemical recurrence-free survival, *OS* overall survival, *DSS* disease-specific survival, *CAB* complete androgen blockade, *LHRH* luteinizing hormone-releasing hormone

10.4 LDR Brachytherapy Boost

ASCENDE-RT [43] Trial compared dose escalated EBRT (46Gy) and LDR brachytherapy to EBRT (78Gy) in intermediate- and high-risk patients showing 5 and 7 years PFS (89% and 86% vs. 84% and 75%, respectively) increase at the cost of late Grade 3+ urinary toxicity (18% vs. 8%).

10.5 Locally Advanced/Very High Risk/Regional

No standard treatment is defined. Randomized trials have established long-term ADT with RT providing better OS than either ADT or RT alone (Table 3).

Subgroup analysis from RTOG 85-31 showed that 95/173 pN1 patients treated with pelvic RT with immediate ADT had better 5-year (54%) and 9-year (10%) PFS rates compared to RT alone ($p < 0.0001$). Multivariate analysis revealed a statistically significant effect on OS [48]. Similar results have been confirmed from the control arm of the STAMPEDE trial in a non-randomized comparison [49].

11 Adjuvant Radiotherapy

Three prospective trials have assessed the role (Table 4).

Table 4 Trials for adjuvant radiotherapy in prostate cancer

Study	n	Inclusion criteria	Randomization	Definition of BCR PSA (ng/mL)	Median F/U (yr)	Biochemical PFS	OS
SWOG 8794[50]	431	pT3cN0 ± involved margins	60–64Gy vs. Observation	> 0.4	12.6	10 year: 53% vs. 30% ($p < 0.05$)	10 year:74% vs. 66% ($p = 0.023$)
EORTC 22911[15]	1005	pT3 ± involved margins pN0; pT2 involved margins pN0	60Gy vs. Observation	> 0.2	10.5	10 year: 60.6% vs. 41% ($p < 0.001$)	10 year: 81% vs. 77% (NS)
ARO 9602[51]	388	pT3 (± involved margins) pN0; PSA post-RP undetectable	60Gy vs. Observation	> 0.05 + confirmation	9.3	10 year: 56% vs. 35% ($p = 0.0001$)	10 year: 82% vs. 86% (NS)

Table 5 Trials for salvage radiotherapy in prostate cancer

Study	n	Risk groups	Median F/U (mo)	Randomization	Outcome
GETUG AFU16[52]	369 RT+ ADT vs. 374 RT	GS ≤ 7 (89%) GS ≥ 8 (11%) cN0	63	66Gy + GnRH X 6 months vs. 66Gy	5 year PFS: 80% vs. 62% ($p < 0.0001$)
RTOG 9601[53]	384 RT + ADT vs. 376 RT	pT2 R1, pT3 cN0	156	64.8Gy + bicalutamide X 24 months vs. 64.8Gy + placebo	12 year DM: 14% vs 23% ($p = 0.005$) 12 year OS: 76% vs 71% ($p = 0.04$)

ADT androgen depravation therapy, *GS* Gleason score, *GnRH* gonadotropin-releasing hormone, *PFS* progression-free survival, *DM* distant metastases, *OS* overall survival, *mo* months

12 Salvage Radiotherapy (SRT)

PSA failure may occur in 15% to 40% of patients after RP. Salvage RT is usually combined with hormonal therapy (Table 5).

12.1 Artistic Meta-Analysis Presented at the ESMO Congress 2019

Across three trials (RADICALS, RAVES, GETUG AFU 17), 1074 men were randomized to adjuvant radiotherapy and 1077 to salvage radiotherapy. Adjuvant RT (ART) did not improve event-free survival (EFS) compared to early salvage RT with a 1% difference in EFS at 5 years. More than 60% of men randomized to eSRT in these trials are yet to start RT. The role for ART in some men from subgroup analyses is yet to be determined [54].

13 Hypofractionation Radiotherapy (HFX)

13.1 Moderate Hypofractionation

Meta-analysis reveals dose escalation (74–80Gy) is associated with higher late GI toxicity compared to lower doses (64–70.2Gy) [55]. Another meta-analysis of 25 studies including >14,000 patients concluded that HFX could be more effective than conventional fractionation [33] as it is more convenient for the patient and economical for the health care system (Table 6).

The CHHiP Trial [56] consolidates the role of moderate hypofractionation as the new standard of care in the treatment of prostate cancer in the UK.

Presently, in North America, NCCN [2] considers moderate hypofractionation using IMRT “an alternative to conventionally fractionated regimens when clinically indicated.”

The AUA/ASTRO/ASCO group recommends moderate HFX for localized prostate cancer patient (of any risk category) as the evidence is strong for its use in the clinics [60].

13.2 Ultra-Hypofractionation (SBRT)

Katz et al. [61] showed that SBRT to a dose of 35–36.25Gy treated with Cyber knife in five daily fractions in early low-risk prostate cancer provides acceptable outcomes and toxicity. Though there is no data presently to suggest benefit to escalation beyond 35Gy. Ten-year BDFS seems higher than with standard IMRT. Scandinavian HYPO-RT-PC [62] trial done for the intermediate risk group presented in ESRTO 37, Barcelona (full publication awaited) seems to be beneficial as well. Trials are on-going in high-risk disease. The recom-

Table 6 Trials for hypofractionated radiotherapy in prostate cancer

Study	n	Median F/U (yr)	Study arms	Technique	Risk groups	ADT	Outcome	Toxicity
CHHiP [56]	3216	5.2	*CRT*—74Gy/37# *HFX*—SSSSSS60Gy/20#, 57Gy/19#	IMRT IGRT optional (53% use)	LR:15% IR: 73% HR:12%	97%	HFX non-inferior	NS

CRT conventional radiotherapy, *HFX* hypofractionated radiotherapy, *NS* not significant, *IMRT* intensity-modulated radiotherapy, *IGRT* image-guided radiotherapy, *3DCRT* 3D conformal radiotherapy, *LR* low risk, *IR* intermediate risk, *HR* high risk, *Gy* Gray; # fractionation, *ADT* androgen depravation therapy

mendation for use of ultra-hypofractionated EBRT in low risk and intermediate risk is graded as "conditional" in the literature reflecting only moderate-quality evidence. With any hypofractionated approach, IGRT is strongly recommended.

13.3 Complications

- Gastrointestinal—Acute toxicity: Proctitis (5%–30%), enteritis, urgency, tenesmus. Resolves within 3–8 weeks. Late toxicity: Persistent diarrhea, rectal urgency or hematochezia. Incidence ≥ Grade 3 toxicity ranges from 1% to 5% [63–65].
- Genitourinary – Acute toxicity: frequency, dysuria, urgency due to cystitis, urethritis or both [63–65]. Resolves within 4 weeks. Late toxicity (uncommon): Urethral strictures, cystitis, hematuria and bladder contracture.
- Sexual dysfunction – In contemporary series, 30%–45% of men become impotent after therapy, with incidence increasing over time [66, 67].
- Insufficiency fractures – physiologic stress to weakened bone.
- Secondary malignancy – Small increase in the incidence of bladder and rectal cancer, with the risk of mortality at 10–15 years being miniscule [68, 69].

14 Chemotherapy

14.1 Metastatic Disease

14.1.1 Castration/Hormone-Sensitive Prostate Cancer (CSPC/HSPC)

Testosterone serves as the main stimulant for prostate cancer growth [70, 71]. Androgen-deprivation therapy (ADT), which is the gold standard for the initial systemic treatment of metastatic prostate cancer, lowers the serum testosterone levels to castration levels. ADT can be achieved with either surgical or medical orchiectomy.

Surgical Orchiectomy

Bilateral orchiectomy rapidly decreases serum testosterone to castrate levels. It is a relatively simple, cost-effective procedure [72]. It is also advantageous in patients in whom a rapid fall in testosterone is indicated in patients with urinary tract outlet obstruction or in impending spinal cord compression. Another important factor for men choosing between surgery and medical treatment is the psychological impact which surgical castration may have. Placement of testicular prostheses or a subcapsular orchiectomy may decrease the psychological effects [73].

Medical Orchiectomy

Medical orchiectomy through its effects on the hypothalamic–pituitary axis decreases testicular production of testosterone. Medical orchiectomy can be achieved by gonadotropin-releasing hormone (GnRH) agonist or GnRH antagonist [74].

GnRH Agonists: GnRH agonists are agents that bind to the GnRH receptors on pituitary gonadotropin-producing cells, causing an initial release of both LH and follicle-stimulating hormone (FSH), causing the testicular Leydig cells to increase the testosterone production. The increased testosterone production causes a 'flare' of disease especially spinal cord compression and urinary tract obstruction [75]. Anti-androgens (Bicalutamide) are combined with GnRH agonists for 2–3 weeks to prevent the flare phenomeneon. GnRH receptors are down regulated after a week [76] and subsequently serum testosterone levels are reduced after 3–4 weeks [77]. Leuprolide, goserlein, buserlein and triptorelin are the GnRH agonists available for use.

GnRH Antagonists: GnRH antagonists (e.g. degarelix) suppress the testosterone levels while avoiding the flare phenomenon. GnRH antagonists like the agonist too bind to the

GnRH receptors on pituitary gonadotropin-producing cells but do not stimulate an initial release of LH or FSH.

14.2 Combinations with Anti-Androgen Therapy

- Docetaxel
- Abiraterone
- Apalutamide
- Enzalutamide

14.3 ADT plus Docetaxel

- There are 3 large RCTs which compared ADT alone as the standard of care with ADT combined with docetaxel (75 mg/sq.m, every 3 weeks) (within 3 months of ADT initiation) along with pre-medicated steroid therapy. Overall survival was the primary objective in all three studies.
- The Chemo-hormonal Therapy versus Androgen Ablation Randomized Trial for Extensive Disease in Prostate Cancer (*CHAARTED*) randomized 790 patients with mHSPC to receive either ADT + docetaxel (75 mg/m^2 every 3 weeks for six cycles) (ADT-DOCE) or ADT alone. The median overall survival was 13.6 months longer with ADT-DOCE than with ADT alone (57.6 months vs. 44.0 months; HR 0.61; 95%CI 0.47–0.80) at a median follow-up of 28.9 months. Other endpoint of study, median time to biochemical, symptomatic, or radiographic progression was 20.2 months in the ADT-DOCE group, as compared to 11.7 months in the ADT-alone group (HR 0.61, 95%CI 0.51–0.72). In a subgroup analysis of patients, the overall survival was increased (51.2 vs. 34.4 months; HR, 0.63; 95% CI, 0.50–0.79; $P < 0.001$) in patients with high-volume disease (defined as presence of visceral metastases or ≥ 4 bone lesions, with ≥1 beyond the vertebral body or pelvis), whereas there was no improvement in OS (63.5 vs. not reached; HR, 1.04; 95% CI, 0.70–1.55; $P = 0.86$) in patients with low-volume disease [78]. In the updated analysis of the trial at a median follow-up 53.7 months, the median OS was 57.6 months for the ADT-Doce group versus 47.2 months for ADT alone (HR,0.72:95%CI,0.59 to 0.89, $p = 0.0018$) Patients with high-volume disease had an OS benefit of 17 months (51.2 v/s 34.4,HR,0.63,95% CI,0.50 to 0.79, $p < 0.001$), while those with low-volume disease did not have an OS benefit (HR, 1.04, 95%CI, 0.70 to 1.55, $p = 0.86$) [79].
- *STAMPEDE* trial [49] is a multiarm, multistage design. Totally, 2962 patients were randomized in 2:1:1:1 ratio into 4 arms—(SOC; ADT alone), SOC + zoledronic acid (SOC + ZA), SOC + docetaxel (ADT-DOCE) or SOC with both zoledronic acid and docetaxel (SOC + ZA + Doc). The patient population comprised 697 (24%) men who were N0M0, 448 (15%) with N+/X M0 and 1817 (61%) men with M+ disease. At the median follow-up of 43 months (IQR 30–60), ADT-DOCE arm showed significant improvement in survival compared with ADT 81 months v/s 71 months (HR 0.78, 95%CI 0.66–0.93), ZA showed no evidence of survival improvement and addition of ZA to ADT-DOCE did not show any overall survival benefit. ZA should not be part of standard of care for this population was the conclusion of this trial. An updated analysis of STAMPEDE recently published, suggest that after median follow-up of 6 years, among 1086 M1 patients, 468 (56%) had high and 362 (44%) had low metastatic burden. There is affirmative evidence of benefit of docetaxel over SOC on OS (HR = 0.81, 95% CI 0.69–0.95, $P = 0.009$) with no evidence of heterogeneity of docetaxel effect between metastatic burden sub-groups (interaction $P = 0.827$). Evidence of benefit was found after analysing other outcomes for docetaxel over SOC in failure-free survival (HR = 0.66, 95% CI 0.57–0.76, $P < 0.001$) and progression-free survival (HR = 0.69, 95% CI 0.59–0.81, $P < 0.001$) with no evidence of heterogeneity of docetaxel effect. The clinically significant benefit in survival for upfront docetaxel persists even after longer follow-up, with no evidence that benefit differed by metastatic burden. STAMPEDE group concluded regardless of metastatic burden in patients with metastatic hormone naïve prostate cancer patients' upfront docetaxel should be considered [80].
- In the *GETUG 15 trial* [81], a total of 385 patients were randomized to ADT or ADT plus Docetaxel. At a median follow-up of 84 months, overall survival was increased in the chemo hormonal arm, but the difference was not statistically significant (62 months vs. 49 months, HR088, 95% CI, 0.68 to 1.14).
- In all three trials, toxicity was mainly haematological, Grade 3–4 neutropenia being around 12%–15% and Grade 3–4 febrile neutropenia around 6%–12%. Febrile neutropenia shows significant reduction by use of granulocyte colony-stimulating factor receptor (GCSF) [82, 83]. Based on these data, docetaxel combined with ADT should be considered as a standard in men presenting with metastases at first visit, provided they are fit enough to receive the drug [49, 78, 81].

14.4 ADT plus Abiraterone

LATITUDE Trial [84] randomized 1199 men with newly diagnosed castration sensitive to ADT plus abiraterone and prednisone or to ADT plus matching placebos. Patients had high-risk disease with the presence of at least two out of three high-risk parameters: Gleason score 8 or higher, at least three bone lesions and the presence of measurable visceral metastasis. At a median follow-up of 52 months, overall survival was significantly increased with the addition of abiraterone plus prednisone (median survival not reached versus 34.7 months, hazard ratio [HR] 0.62, 95% CI 0.51–0.76). Abiraterone arm had higher incidence of grade3 or more hypertension and hypokalemia.

STAMPEDETrial [49]: One thousand nine hundred and seventeen men were randomly assigned to ADT plus abiraterone and prednisone or to ADT alone. The overall survival was significantly increased with the addition of abiraterone (3-year survival 83 versus 76% with ADT alone, HR 0.63, 95% CI 0.52–0.76). The failure-free survival was also significantly increased in the ADT plus abiraterone arm of the trial (3-year failure-free survival rate 75 versus 45, HR 0.29, 95% CI 0.25–0.34).

14.5 ADT plus Enzalutamide

ENZAMET(ANZUP 1304) [85]: Phase III trial randomized standard-of-care therapy with or without enzalutamide for metastatic hormone-sensitive prostate cancer (mHSPC). In total, 1125 patients were randomized to receive ADT plus either ENZA or NSAA (NSAA: bicalutamide, nilutamide or flutamide) with or without docetaxel. The overall survival was significantly prolonged in the enzalutamide arm compared to the non-steroidal anti-androgen arm (HR 0.67, 95% CI 0.52–0.86) after a median follow-up of 34-month. Concurrent enzalutamide and docetaxel had more toxicity, and this subgroup did not have survival benefit.

14.6 ADT plus Apalutamide

TITAN was phase 3, double-blind trial of 1052 metastatic, castration-sensitive prostate cancer patient who received either apalutamide (240 mg per day) or placebo, added to ADT. The primary end points were overall survival and radiographic progression-–free survival. At the first interim analysis with a median follow- up of 22.7 months, radiographic progression-free survival at 24 months was 68.2% in the apalutamide group and 47.5% in the placebo group (hazard ratio for radiographic progression or death, 0.48; 95% confidence interval [CI], 0.39 to 0.60; $P < 0.001$). The frequency of grade 3 or 4 adverse events was 40.8% in the placebo group, 42.2% in the apalutamide group and; rash was more common in the apalutamide group. Apalutamide was approved for treatment of metastatic castration-sensitive prostate cancer in the United States in September 2019 based on the TITAN trial [86].

14.6.1 Castration-Resistant Prostate Cancer (CRPC)

Definition

Disease progression on androgen-deprivation therapy (ADT) castrate serum testosterone <50 ng/dL or 1.7 nmol/L plus either

(a) Biochemical progression: Three consecutive rises in PSA 1 week apart resulting in two 50% increase over the nadir and a PSA > 2 ng/mL or,

(b) Radiological progression: The appearance of new lesions: Either two or more new bone lesions on bone scan or a soft tissue lesion using RECIST (Response Evaluation Criteria in Solid Tumours) [87].

The pattern of disease includes non-metastatic (M0 with rising PSA and disease limited to prostate or metastatic (M1) which includes bone metastasis, nodal metastasis and visceral metastasis with or without bone metastasis.

14.7 Non-Metastatic CRPC

Apalutamide or enzalutamide are approved for non-metastatic CRPC.

Apalutamide: In a phase 3 SPARTAN trial,[88] 1207 patients of non-metastatic CRPC with a PSA doubling time ≤ 10 months were randomized in a 2:1 ratio to receive apalutamide (240 mg per day) or placebo. The primary end point was metastasis-free survival (MFS). At the time of planned primary analysis, MFS was 40.5 months in the apalutamide group as compared with 16.2 months in the placebo group (hazard ratio for metastasis or death, 0.28; 95% confidence interval [CI], 0.23 to 0.35; $P < 0.001$). The rate of adverse events leading to discontinuation of the trial regimen was 10.6% in the apalutamide group and 7.0% in the placebo group.

Enzalutamide: In a phase 3 study (PROSPER), [82] 1401 patients with M0 CRPC with a PSA doubling time ≤ 10 months and PSA ≥2 ng/mL were randomized (2:1) to enzalutamide 160 mg per day or placebo. The median metastasis-free survival was 36.6 months in the enzalutamide group versus 14.7 months in the placebo group (hazard ratio for metastasis or death, 0.29; 95% confidence interval, 0.24 to 0.35; $P < 0.001$). Adverse events of grade 3 or higher occurred in 31% of the patients receiving enzalutamide as compared with 23% of those receiving placebo.

14.8 Metastatic CRPC

In metastatic CRPC, multiple agents have shown benefit in addition to continued ADT:

- Next-generation antiandrogens.
- Chemotherapy.
- Immunotherapy.
- Bone-targeted agents.
- PARPi in men with DNA mismatch repair mutation.

14.8.1 Abiraterone

Chemotherapy-Naive

Abiraterone was evaluated in chemo-naïve 1088, asymptomatic or mildly symptomatic CRPC patients in the phase III trial COU-AA-302. Patients were randomized to abiraterone or placebo, both combined with prednisone (5 mg twice daily). Radiographic PFS (rPFS) and overall survival were the co-primary endpoints. After a median follow-up of 22.2 months, there was significant improvement of rPFS (median 16.5 vs. 8.2 months, HR: 0.52, $p < 0.001$). The OS endpoint was significantly positive (34.7 vs. 30.3 months, HR: 0.81, 95% CI: 0.70–0.93, $p = 0.0033$) at the final analysis with a median follow-up of 49.2 months. Adverse events (AEs) related to mineralocorticoid excess and liver function abnormalities were more frequent in abiraterone arm [83].

Post-Docetaxel

In a phase III trial (COU-AA-301), 1195 patients who had progression of disease over initial docetaxel received 1000 mg abiraterone plus prednisone or placebo. The median survival in the abiraterone group was 15.8 months compared to 11.2 months in the placebo arm (HR: 0.74, $p < 0.0001$) after a median follow-up of 20.2 months. The benefit was observed in all subgroups, and all the secondary objectives favoured abiraterone (PSA, radiologic tissue response, time to PSA or objective progression). Common Grade 3–4 AEs did not differ significantly between arms. As expected, mineralocorticoid-related side effects (fluid retention, oedema and hypokalaemia) were more frequent in the abiraterone group, and majority of SAE were mainly Grade 1–2 [89].

14.8.2 Enzalutamide

Chemotherapy naïve

A randomized phase III trial (PREVAIL) [90] compared enzalutamide and placebo in a chemo-naïve CRPC population of 1717 men and showed a significant improvement in both co-primary endpoints, rPFS (HR: 0.186; CI: 0.15–0.23, $p < 0.0001$) and OS (HR: 0.706; CI: 0.6–0.84, $p < 0.001$). The most common clinically relevant AEs were hypertension and fatigue.

Post-Docetaxel

In AFFIRM phase III trial of 1199 patients who had received prior docetaxel therapy was randomized 2:1 to enzalutamide 160 mg/day orally or placebo. The median survival in the enzalutamide group was 18.4 months compared to 13.6 months in the placebo arm (HR: 0.63, $p < 0.001$) after a median follow-up of 14.4 months. The secondary endpoints QoL, time to PSA or objective progression, PSA reduction and soft tissue response favoured enzalutamide. Side effects were similar in both groups with only difference in seizure which was seen in 0.6% patients in enzalutamide arm [91].

14.8.3 Docetaxel

Docetaxel (75 mg/m^2) given every 3 weeks in combination with daily prednisone (5 mg twice a day) significantly prolonged overall survival compared with mitoxantrone plus prednisone in the TAX 327 phase III trial. 1006 men with mCRPC and good performance status were randomized to receive 5 mg prednisone twice daily and either docetaxel 75 mg/m^2 every 3 weeks; docetaxel 30 mg/m^2 weekly or; mitoxantrone 12 mg/m^2 weekly. The treatment was planned for up to 10 cycles of 3 weeks for the D3P arm and up to five cycles of 6 weeks for the D1P arm. Updated results showed a similar median survival benefit for docetaxel every 3 weeks v. mitoxantrone, with 3-year survival rates of 18.6% and 13.5%, respectively ($p = 0.005$). The magnitude of benefit associated with docetaxel plus prednisone treatment for CRPC was independent of age, performance status or baseline PSA [92].

14.8.4 Cabazitaxel

TROPIC trial was a phase III that compared cabazitaxel plus prednisone was to mitoxantrone plus prednisone in 755 patients with mCRPC, who had progressed after or during docetaxel-based chemotherapy. Patients received a maximum of ten cycles of cabazitaxel (25 mg/m^2) or mitoxantrone (12 mg/m^2) plus prednisone (10 mg/day). Overall survival was significantly longer with cabazitaxel (median: 15.1 vs. 12.7 months $p < 0.0001$) [93]. The PROSELICA trial evaluated two doses of cabazitaxel, 20 mg/m^2 versus 25 mg/m^2. It was a noninferiority trial. The lower dose was found to be noninferior and associated with fewer adverse events setting a new standard of care [94].

The CARD trial evaluated cabazitaxel in the third-line setting. Totally, 255 patients who had previously received docetaxel and an androgen-signaling-targeted inhibitor (abiraterone or enzalutamide) were randomized in 1:1 ratio to receive cabazitaxel (at a dose of 25 mg per square meter of body-surface area intravenously every 3 weeks, plus prednisone daily and granulocyte colony-stimulating factor) or the other androgen-signaling-targeted inhibitor (either 1000 mg of abiraterone plus prednisone daily or 160 mg of enzalutamide daily). The primary end point was imaging-based progression-free survival. Secondary end points of survival, response and safety were assessed. After a median follow-up of 9.2 months, the median imaging-based progression-free survival was 8.0 months with cabazitaxel and 3.7 months with the androgen-signaling-targeted inhibitor (HR, 0.54, 95% CI, 0.40 to 0.73; $p < 0.001$). Adverse events of grade 3 or higher occurred in 56.3% of patients receiving cabazitaxel and in 52.4% of those receiving an androgen-signaling-targeted inhibitor [95].

14.8.5 Sipuleucel-T

Sipuleucel-T is a dendritic cell vaccine that is prepared from peripheral blood mononuclear cells. A phase III trial tested Sipuleucel-T against placebo in 512 asymptomatic or minimally symptomatic CRPC patients where after a median follow-up of 34 months, and the median survival was 25.8 months in the Sipuleucel-T group compared to 21.7 months in the placebo group, with a HR of 0.78 ($p = 0.03$) [96].

14.8.6 Pembrolizumab

KEYNOTE-199 is a phase II trial that enrolled 255 patients with mCRPC treated with docetaxel and one or more targeted endocrine therapies in three cohorts. Cohorts 1 and 2 enrolled patients with RECIST-measurable PD-L1-positive and PD-L1-negative disease, respectively. Cohort 3 enrolled patients with bone-predominant disease, regardless of PD-L1 expression. All patients received pembrolizumab 200 mg every 3 weeks for up to 35 cycles. The primary end point was objective response rate. Pembrolizumab showed an objective response rate of 5% (95% CI, 2% to 11%) in cohorts 1 and 3% (95% CI, < 1% to 11%) in cohort 2. Treatment-related adverse events occurred in 60% of patients, were of grade 3 to 5 severity in 15% and led to discontinuation of treatment in 5% [97].

14.8.7 Radium-223

Radium-223 is a bone-targeted alpha-particle-emitting radioisotope. ALSYMPCIA is a phase III trial that tested Radium-223 against placebo in over 900 men with bone-predominant, symptomatic CRPC without visceral disease and no previous exposure of docetaxel. Radium-223 improved overall survival (HR 0.70; 95% CI 0.58–0.83) and time to first symptomatic skeletal event (HR 0.66; 95% CI 0.52–0.83) [98].

14.8.8 PARP Inhibitors

All men with metastatic prostate cancer should undergo germline testing and those with germline or somatic DNA repair mutation have an option of treatment with a poly-adenosine diphosphate-ribose polymerase (PARP inhibitor).

PRO found trial of randomized metastatic castration-resistant prostate cancer (mCRPC) with homologous recombination repair (HRR) gene alterations in a 2:1 ratio to olaparib (300 mg bid) or the physician's choice of enzalutamide (160 mg/day) or abiraterone (1000 mg/day + prednisone 5 mg BID). The primary endpoint was radiographic progression-free survival (rPFS). Two hundred forty-five randomized to Cohort A. Olaparib was associated with improved rPFS compared to enzalutamide/abiraterone among patients in Cohort A (HR 0.34, 95% CI 0.25–0.47), which was consistent across the majority of subgroups assessed. The interim results for overall survival (OS) demonstrated improved survival among patients in Cohort A (HR 0.64, 95% CI 0.43–0.97) [99].

VC	Verrucous carcinomas
VEIL	Video endoscopic inguinal lymphadenectomy

1 Introduction

Penile cancer (PeCa) is seen uncommonly in today's time in most parts of the world. It commonly affects poor socioeconomic group in developing countries. Many seek a delayed opinion in spite of noticing the lesion thereby leading to advanced disease at presentation. The treatment guidelines do not have many recommendations from randomized studies. Concerns regarding PeCa include delayed diagnosis, penile preservation, decisions in advanced disease, treatment related side-effects, and palliation.

2 Incidence and Epidemiology in India and Globally

The incidence in most part of the western world is decreasing in recent decades. The age-adjusted incidence is less than 1/100000 in Europe and North America, but in certain part of south America, Africa, and Asia, it is as high as 12/100000 [1]. In Europe, a recent review recorded the incidence of 0.58/100000 men. Brazilian cities of Sao Paulo and Recife have a higher incidence as well as Uganda [2, 3]. Lowest incidence has been in the Jewish community (0.1/100000) and may be due to the prenatal circumcision in Jews [4]. Low socioeconomic status and bad hygiene are associated with most cases [2, 4].

In India, PeCa account for approximately 1% of male cancers. It affects around 7% of men in the third decade and 19% in the fifth decade [2, 5, 6]. The disease is usually common in the fifth to seventh decades but occurs a decade or two earlier in developing nations [3].

2.1 Risk Factors and Premalignant Conditions

The risk factors strongly identified for PeCa are phimosis, chronic irritative and inflammatory condition such as balanitis Xerota obliterans (BXO) and balanoposthitis and association with human papilloma virus (HPV) 16 and 18 [7].

HPV association is present in more than 50% of cases with in situ, basaloid, verrucous penile carcinoma. Lichen sclerosus atrophus (also known as BXO) is associated with non-HPV PeCa [7]. Neonatal circumcision seems to have a protective role [8, 9]. Smegma was found to be carcinogenic in animal studies, but in human-related studies there is no relation with PeCa [10].

Badwe RA, Gupta S, Shrikhande SV, Laskar S (eds.), *Tata Memorial Centre Textbook of Oncology*,
https://doi.org/10.1007/978-981-99-3378-5_52

Cigarette smoking is strong risk factor and has a 2.4–4.5 times the risk than nonsmokers and is directly proportional to number of cigarettes [11, 12].

Studies have been done about the relation of sexual relation with PeCa. Male partners of females with cervical intraepithelial neoplasia have a higher incidence of penile intra epithelial carcinoma. Also, males with early age of first intercourse and multiple sexual partners have a three- to five-fold increased risk [13].

HPV is known to alter the genomes thereby disturbing balance between oncogenes and tumor suppressor genes. There is 5-year survival advantage in PeCa associated with HPV DNA positive (78% vs. 93%, log rank test $P = 0.03$) [14]. There has also been an association between patients of condyloma acuminata and PeCa.

2.2 Premalignant Condition

Cuteneous horn, hyper keratotic dysplasia, giant condyloma (Buschke lowenstien tumor), pseudoepitheliomatosis, micaceous and keratotic balanitis, leukoplakia, BXO, and carcinoma in situ (Erythroplakia of Queyrat, Bowen's disease, and Bowenoid papulosis) are premalignant condition for PeCa [7, 15, 16].

3 Clinical Presentation in India and Globally

Patient with PeCa may present with localized, locally advanced or metastatic disease.

Patient may have phimosis and a lesion hidden below. In case it goes unnoticed, it can erode foreskin and grow further. Foul preputial odor and discharge with or without bleeding may be present.

Penile lesion may present in various forms—small papule, pustule and warty growth, and exophytic lesion, shallow or deeply excavated ulcer with elevated or rolled up edges (Fig. 1).

Inguinal mass, either enlarged or fungated nodes, may be another presentation. Occasionally, ulceration, suppuration, or hemorrhage is seen from nodal mass. Rare presentation would be urinary retention or urethral fistula.

Pain is not a presenting complaint. Weakness, weight loss, fatigue, and systemic malaise occur secondary to chronic suppuration or advanced disease. Because local disease and regional disease are usually far advanced by the time distant metastases occur, presenting symptoms referable to such metastases are rare.

In India,about three-fourths patients were older than 50 years. About 25% patients presented with phimosis and 20% patients had undergone circumcision after attaining adulthood.

Most patients presented with T2 disease, whereas palpable nodes, benign or malignant, were present in 55.5% and 76% patients in T1 and T2 patients, respectively [17].

Penile tumors occur most commonly on the glans (48%) and prepuce (21%) with involvement of glans and prepuce (9%), the coronal sulcus (6%), or the shaft (<2%) [18]. This distribution of lesions may be the result of constant exposure of the glans, coronal sulcus, and interior prepuce to irritants (e.g., smegma, HPV infection) within the preputial sac, whereas the shaft is relatively spared.

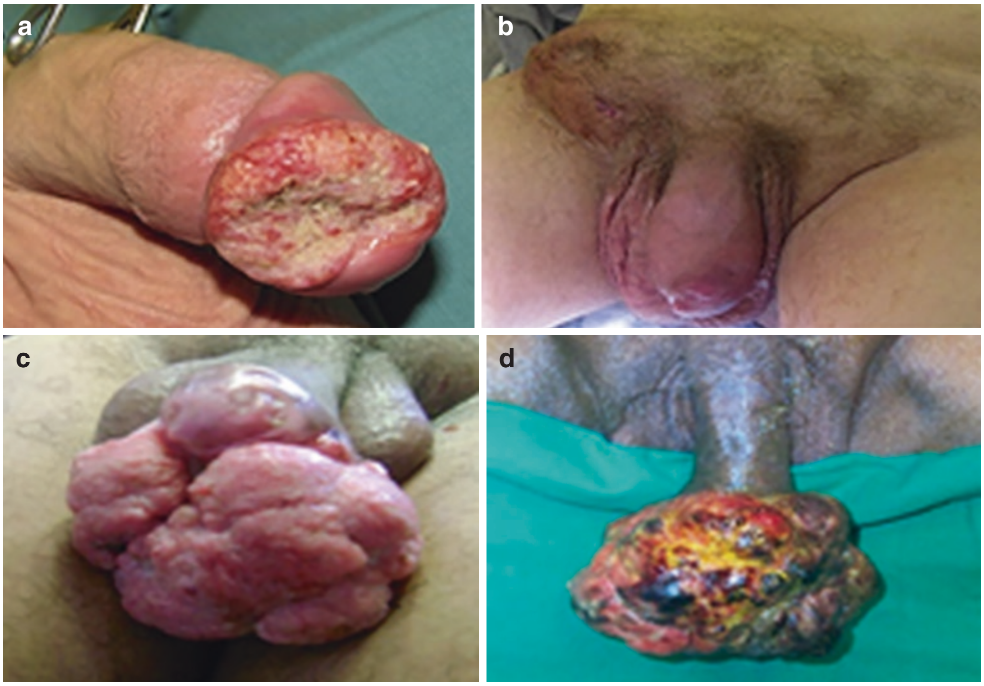

Fig. 1 (**a**–**d**) Penile lesions

4 Evaluation and Work-up

4.1 Diagnosis

1. Examination—Primary lesion described with respect to its site (preputial/penile shaft), appearance (verrucous/warty/ulcerative, invasive), size, and urethral/corporal involvement. Bilateral groin areas to be examined. Lymph nodes can be reactive in case of an infected penile lesion and at times they can be hard suggesting malignant spread [15].
2. Biopsy of penile lesion—Pathological diagnosis is mandatory.
3. Fine needle aspiration cytology (FNAC)—Cytology in enlarged or suspicious node or USG guided. High-frequency USG can help characterize nodes when indeterminate or in obese patients and also give information on pelvic nodes. It has a sensitivity of 39% and specificity of 100%. With significant false-negative rates, if FNAC is negative and clinical suspicion is high, a repeat FNAC or excisional biopsy can be done [19].
4. Magnetic resonance imaging (MRI)—In tumors extending on the root of penis, a good investigation for delineating extent and infiltration. Even gives better resolution of soft tissues and vasculature around enlarged nodes. MRI with lymphotropic nanoparticle (Ferrumoxtran-10) has shown a sensitivity of 100% and specificity of 97% in identifying occult metastases in a small series [20].
5. Computerized tomography (CT) scan—Usually done to assess lymph nodes.
6. Fluorine 18 fluorodeoxyglucose (FDG) positron emission tomography (PET) CT—Not routinely used, but has a good sensitivity ~90% and specificity ~100%, to Ca penis and its lymph node spread. In many small studies, it has been shown to be useful. PET CT has shown to be a promising investigation which can identify early metastases and is useful in following up groin of patients with Ca penis after primary treatment [21]. In patients with large palpable groin nodes, it can be a good investigation [22]. However, in patients with clinically normal groins, the sensitivity drops down to 20% [23].
7. Tumor markers—Biomarkers are used to estimate biological behavior [24], but rarely used due to suboptimal value. Currently, biomarkers do not have a routine place in current management of PeCa [25]. Available biomarkers are summarized below:
    (a) Plasmatic—Squamous cell carcinoma antigen (SCCAg) and C-reactive protein (CRP).
    (b) Proliferative—Ki-67 and proliferating cell nuclear antigen, HPV causes overexpression of E6 and E7 viral oncogenes, tumor suppressor gene TP53.
    (c) Cytogenetic—MYC gene and CDKN2A.

4.2 Pathology

Most primary malignant tumors of penis are squamous cell carcinomas (SCC) originating in the epithelium covering the glans, coronal sulcus, and inner foreskin. Glans tumors predominate over those exclusive of the foreskin or sulcus. Pathologically SCC may reveal varied patterns of growth like superficial spreading, vertical growth pattern, verruciform, and multicentric growth pattern. Of these, the vertical pattern has the most propensity to metastasize.

The various histologic subtypes seen in PeCa as below [26–30].

Squamous Cell Carcinoma: Most common, more than 70% cases. Microscopically, an infiltrating keratinized squamous carcinoma of moderate differentiation is noted.

Basaloid Carcinoma: Basaloid carcinoma is an aggressive, high-grade, and deeply invasive penile neoplasm, usually associated with HPV. More than half the patients have metastatic inguinal nodes at the time of diagnosis.

Verrucous Carcinomas (VC): VCs are slow-growing and grossly appear as exophytic, cauliflower like gray-white mass. The tumor can be locally aggressive, but it is biologically benign and should be treated accordingly.

Warty (Condylomatous) Carcinoma: Warty carcinomas are slow-growing, nonaggressive, verruciform HPV-related tumors.

Papillary Carcinoma (PC): PC is a type of low-grade verruciform carcinoma, lacking distinctive diagnostic features and having no association with HPV.

Sarcomatoid Carcinoma: Sarcomatoid carcinomas are rare, aggressive, large neoplasms predominantly composed of spindle cells.

Adenosquamous Carcinoma: Adenosquamous carcinoma is quite rare carcinoma which originates in misplaced glandular cells in the perimeatal region of the penis.

Carcinoma Cuniculatum: They are low-grade SCCs, which because of their "burrowing growth" are called as cuniculatum. Despite the deep penetration, none of the reported carcinoma cuniculatum cases showed groin or systemic metastases.

*Pseudohyperplastic Carcinom*a: It is a low-grade SCC preferentially affecting the foreskin of older patients in association with lichen sclerosus and usually they do not metastasize.

Acantholytic (Adenoid, Pseudoglandular) Carcinoma: These are high-grade, large, irregular masses involving multiple penile anatomical compartments and deeply invading having a higher incidence of regional metastases and mortality.

Clear Cell Variant of Penile Carcinoma: Very uncommon, linked with HPV, early metastasis, poor prognosis, lesion-dependent outcome, frequent lymphatic metastases—indicates a benefit of preventive lymphadenectomy for patients with clear-cell carcinomas [31].

Other Mixed Neoplasms: SCC can be found in association with any other subtypes of PeCa. Mixed carcinomas account for about 25% of PeCa.

5 TNM Staging of Penile Cancers [32]

The anatomic stage and prognostic groups stagings can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 706–707, Chapter no. 57, Penis, Table: Definition of TNM and AJCC prognostic stage groups and which can be accessed at https://www.pathologyoutlines.com/topic/penscrotumpenisstaging.html and https://www.cancerresearchuk.org/about-cancer/penile-cancer/stages-types-grades/tnm-staging

6 Principles of Management

The aim of treatment is first to take care of cancer as per oncological principles and secondly to try organ and functional preservation methods while being careful of the first aim. A safe surgical margin is necessary in case of surgical amputation. The earlier concept of a 2-cm margin has given way to around 1 cm margin. In patients where penile stump length is short, a margin lesser than 1 cm is acceptable, but these are tailor made decisions after due preoperative counseling of patient and his family. For a general recommendation, 3–5 mm can be considered safe maximum [33].

Stage of disease and presence of lymph node metastasis (LNM) remain the most important prognostic factors for disease outcome. Histological subtype, grade, perinodal extension, and lymphatic and/or venous embolization are the most important variables that predict inguinal LNM [34].

7 Surgical Management

For small lesions, less invasive surgery such as wide surgical excision with cold knife or CO2 laser, cryotherapy, radiation, Mohs's micrographic technique should be attempted. Other options include topical 5FU and 5% imiquimod applications and photodynamic therapy [35].

In preputial lesions either only circumcision or additional excision of part of glans penis might be required.

In slightly bigger lesions, a glansectomy or a partial amputation of penis would be necessary (Fig. 2). Even in partial penectomy, a good stump for sexual function and upright micturition should be achieved. In few cases, a total amputation of penis with a perineal urethrostomy is required (Fig. 3) [36].

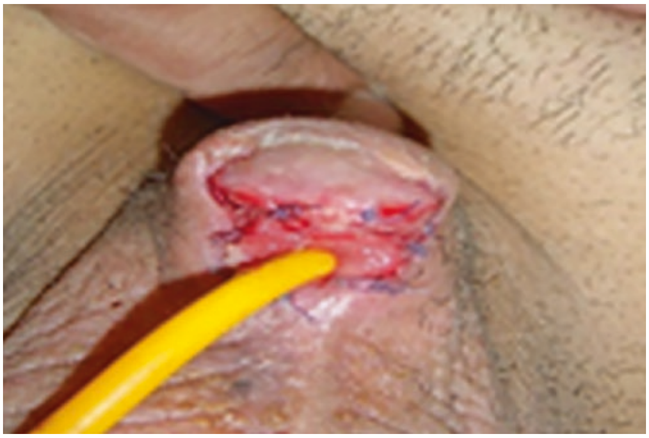

Fig. 2 Partial penectomy

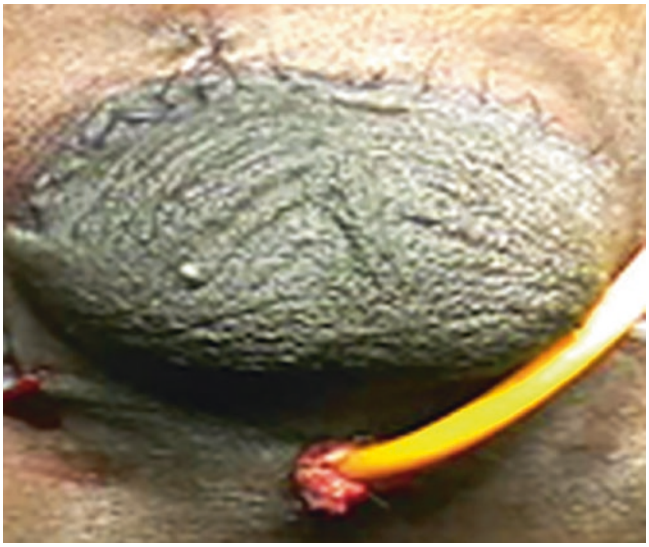

Fig. 3 Total penectomy with perineal urethrostomy

Generally, large widely infiltrative tumors have a poorer prognosis due to involvement of adjacent structures—lymphatics, lymphatic emboli, and involvement of vascular structures like corpora and blood vessels.

Radiation therapy should be given in few select patients with less than 4 cm superficial lesions with special techniques employed during the therapy. The complications include urethral stricture, penile necrosis, and recurrence [37].

8 Management of Lymph Nodes

20–25% of patients with clinically normal groins harbor occult metastases. In patients with palpable inguinal nodes, 70% of patients have metastases. In the remainder, nodes are enlarged due to infection. The traditional teaching of 6 weeks of antibiotics followed by reassessment of inguinal reassessment has been abandoned now to avoid a delay in diagnosis [38, 39].

8.1 Relevant Anatomy

Lymphatic drainage from penis parallels with superficial venous system that drains skin, glans and corporal bodies. The superficial inguinal nodes have been divided into five zones by drawing a horizontal and a vertical line through the point where the saphenous vein drains into the femoral vein with one zone directly overlying the junction. The smaller deep inguinal region is deep to the fascia lata along the medial aspect of the femoral vessels. Based on lymphangiographic studies, Cabanas described a sentinel lymph node located super medial to the epigastric-saphenous junction [40, 41].

Chaux et al. devised a prognostic index based upon histologic grade, extent and depth of tumor invasion, and perineural invasion. This group has proposed a scoring system to identify high risk patients likely to develop nodal metastasis in whom a prophylactic nodal dissection is advised [30].

If a malignant node is found on biopsy care should be taken to excise biopsy tract during subsequent lymphadenectomy [40].

8.2 Management of Patients with Clinically Normal Groin

Patients with clinically normal groins may harbor occult metastases in inguinal nodes. Risk stratification based on T stage and grade is an important tool to predict inguinal node involvement and survival in patients with clinically N0 inguinal nodes [42].

An optimum management strategy of these patients would be to offer early surgery and at the same time does not over treat patients unlikely to have nodal disease. Early surgical resection of inguinal nodes has therapeutic benefit. Inguinal lymph node dissection (ILND) has a reported complication rate ranging from 35 to 88%. So, patient selection is of prime importance when performing ILND in patients with clinically normal groins [43, 44].

In patients with clinically normal groins, three approaches of treatment are available. These are

1. Surveillance.
2. Dynamic sentinel lymph node biopsy (DSNB).
3. Modified inguinal lymph node dissection (MILD).

Risk-adapted approaches have been recommended by European Association of Urology to choose one or more of the above treatment options.

Surveillance can be offered to patients reliable for follow-up and with either low-risk or selected intermediate-risk patients.

8.3 Dynamic Sentinel Lymph Node Biopsy (DSNB)

The concept of sentinel node biopsy as proposed by Cabanas in 1977 initially was abandoned due to a large number of false negatives. This technique was revived later in 1992 by use of isosulphan blue dye as tracer and preoperative radioactive tracer (Technetium 99 m labeled nano colloid) in melanoma patients. Recently, with refinement of technique, a sensitivity of 93% and specificity of 100% has been reported from a two center prospective series of 323 patients. DSNB is recommended by European Association of Urology for all patients with intermediate or high-risk disease [45, 46].

8.4 Modified Inguinal Lymphadenectomy

MILD was first described in 1988 in an attempt to remove the nodes most likely to harbor tumor and to reduce the morbidity associated with complete inguinal node dissection. As originally described, this procedure consisted of a shorter skin incision, preservation of the subcutaneous tissue superficial to Scarpa's fascia, no dissection lateral to the femoral artery or caudal to the fossa ovalis, preservation of the saphenous vein, and elimination of Sartorius muscle transposition (Fig. 4). In a recent study evaluating follow-up (mean 78 months) of patients undergoing MILD, it was found that it has a significantly reduced complication rate compared to complete node dissection. However, despite a negative frozen section analysis bilaterally, 5.5% of inguinal regions were found to harbor occult metastases. Also, a minimum follow-up of 2 years following MILD has been sug-

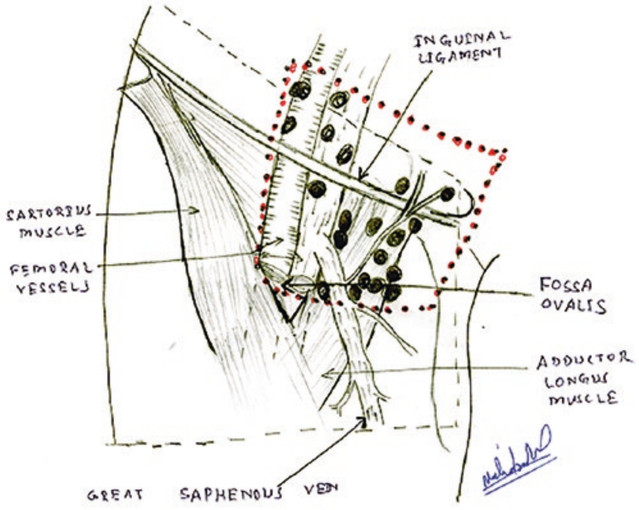

Fig. 4 Modified inguinal lymph nodes dissection boundaries

gested by the authors as all recurrences were within this period [47, 48].

8.5 Management of Patients with Node-Positive Disease

Complete ILND should be done if positive nodes are found on FNAC, excision biopsy, DSNB, or MILD. Complete ILND as described by Daseler is demarcated by four lines (Fig. 5).

Superior: from the anterior superior iliac spine to the external inguinal ring.

Lateral: From the anterior superior iliac spine extending 20 cm inferiorly.

Medial: From the pubic tubercle 15 cm inferiorly.

Inferior: Connecting the lower ends of the second and third lines.

The boundaries of dissection are as follows:

- Proximally: Inguinal ligament.
- Distally: Crossing of the Sartorius muscle and the adductor longus muscle (also referred to as the entrance of the Hunter canal, where the femoral vessels go under the muscles of the leg).
- Medially: Adductor muscle.
- Laterally: Sartorius muscle.

The floor of the dissection consists of the fascia lata, the femoral vessels, and the pectineus muscle.

The dissection should not be performed posterior to the vessels or around the femoral nerve. Sartorius muscle can be transposed medially to cover the femoral vessels.

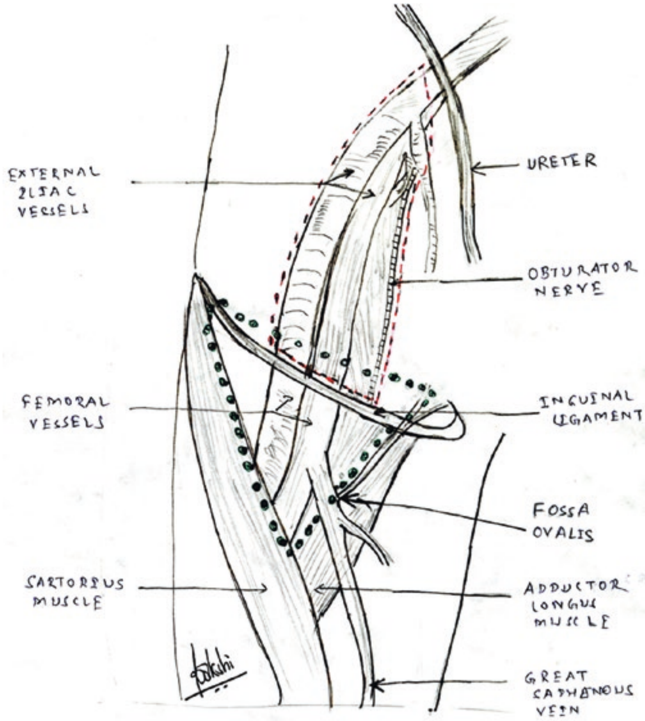

Fig. 5 Ilioinguinal lymph nodes dissection boundaries [1]. Deep inguinal lymph node dissection [2]. Pelvic lymph node dissection

8.6 Pelvic Lymph Node Dissection (PLND) [49]

Twenty to thirty percent of patients with positive inguinal nodes have positive pelvic nodes. An ipsilateral PLND of the affected site should be done in all patients with two or more inguinal nodes involved or with extranodal extension. Contra lateral PLND is not recommended in patients with unilateral nodal involvement as crossover from the groin to contralateral pelvic area is not known to happen. The boundaries of the PLND are as follows:

- Proximally: Common iliac vessels.
- Distally: The passage of lymphatic vessels to the groin,
- Laterally: Ilioinguinal nerve.
- Medially: Urinary bladder and prostate.
- Base: Deepest part of the obturator fossa.

8.6.1 Inguinal Wounds Post Groin Node Dissection

A primary closure if edges can be easily approximated after a Sartorius flip to cover vascular structures. If edges are under tension or apart, a pedicled anterolateral thigh flap is used to cover the defect.

8.7 Timing of Inguinal Lymphadenectomy

Inguinal lymphadenectomy (ILND) is known as early or prophylactic in CN0, generally within 6 weeks of treatment of primary and delayed or therapeutic when performed for development of palpable inguinal nodes during follow-up. Reviews of the published data showed a 5-year survival rate of 57–88% for early and 8–38% for delayed LND. Several investigators have concluded that delayed lymphadenectomy has a significantly decreased survival and is not recommended [50–52].

Whether ILND should be performed at same sitting as penectomy or after an interval of giving antibiotics had also been a subject of debate. Recent studies have failed to show any difference in operative morbidity if lymphadenectomy is done after 6 weeks of antibiotics hence it is suggested that inguinal lymphadenectomy can be done with primary surgery [53].

8.8 Complications of Inguinal Lymph Node Dissection

Complication rates ranging from 35 to 88% have been reported following ILND. Associated pelvic node dissection and use of radiotherapy have shown increased complication rates. Most common complications are wound infection with or without dehiscence (14 ± 50%), lymphocele/seroma (10 ± 10%), lymphedema, deep vein thrombosis, femoral neuropraxia, myocardial infarction, and rarely death [52].

8.9 Minimally Invasive Inguinal Lymphadenectomy

Video endoscopic inguinal lymphadenectomy (VEIL) has been tried in an attempt to reduce morbidity related to lymphadenectomy. In a recently published series of 33 VEIL performed in 20 men with a mean follow-up 20 months, the average operative time was 119 minutes and mean resected lymph nodes was 8 per lymphadenectomy. The overall complication rate was 33.2%. No patient had skin necrosis. The lymphatic complication rate was 27.2%.The overall survival rate was 80%, and cancer-specific survival was 90% [54]. Robotic VEIL is also described.

9 Medical Management

9.1 Chemotherapy

PeCa patients with large fixed, fungating, and sometimes fixed nodes are likely to have systemic disease, either occult or manifest. Surgery alone is not going to be curative and hence the role of multimodal treatment. Various drug combinations of cisplatin, fluoropyrimidines, gemcitabine, paclitaxel, bleomycin, methotrexate, and irinotectan have been put to use as neo adjuvant or adjuvant chemotherapy. Platinum-based chemotherapies have been the most active agents and have been always used in combinations. Earlier such studies had a survival of 3–11 months [55]. A response rate of 50% is achieved in neo adjuvant chemo therapy (NACT) with platinum combination therapies in fixed and locally unresectable groin nodes [56].

Adjuvant chemotherapy[AC] is given in pN2/pN3 patients and Pizzocaro et al. reported long-term disease-free survival(DFS) with AC than without AC in pN+ patients; 84% vs 39%.

5-Fluorouracil (5-FU) plus paclitaxel or docetaxel regime has shown a promising 52.6% DFS in median follow-up of 42 months. In patients with diagnosed PeCa metastases, prognosis is very poor but few series have reported a response rate of 30.8%. Chemo radiation is currently advised as a part experimental clinical scenario [57].

Avelumab (PDL1) and pembrolizumab (PD1) are being evaluated in 2 small phase II trials. TKI inhibitor dacomitinib has shown a response of 32% in similar circumstances. The results with these agents are quite promising [58].

The French study AFU-GETUG 25 (NCT02817958) is currently enrolling patients and aims to assess a multimodal approach for lymph node metastasis in penile SCCs—lymphadenectomy and adjuvant chemotherapy vs neoadjuvant chemotherapy followed by bilateral lymphadenectomy.

InPACT (NCT02305654) aims to determine prospectively the relative benefits and sequencing of surgery, chemotherapy, and chemoradiotherapy in the management of patients with penis cancer who present with palpable or radiologically evident inguinal lymph node metastases [59].

9.2 Radiation Therapy (RT)

9.2.1 RT for the Primary

Selected cases in PeCa, T1-2 lesions <4 cm, can be offered therapeutic radiation with the aim of cure and organ preservation. External RT of 60Gy using a penile mould, with brachytherapy (BT) boost or 55-60Gy dose in brachytherapy alone is used [60]. BT has good results reaching local cure rates of 90% with functional preservation and negligible morbidity [61].

A meta-analysis proved small benefit in favor of surgery than BT, 5 years OS being 76%vs 73%, and local cure rates of 84% vs 79% [62]. Glans necrosis, delayed corporal body fibrosis, urethral and meatal stenosis, and painful intercourse are some of the side effects of RT.

9.2.2 RT for Nodal Disease

RT to postoperative nodal regions is not suggested in pN_{2-3}. It can better the loco regional control of disease but with associated morbidity. Winters et al. also reported survival benefit with adjuvant RT [63]. In unresectable disease, it can be used as a method of palliation.

9.3 Role of Targeted Therapy

Anti-programmed death 1 (PD1), anti-PD-L1, and anticytotoxic T-lymphocyte antigen 4 (CTLA4) immunotherapy have emerged as a viable treatment option for a range of malignancies, including HPV-related neoplasms such as head and neck cancer.

Drug Avelumab—role in penile cancer patients—ongoing trials include the Phase II ALPACA trial (NCT03391479), which is actively enrolling patients with locally advanced or metastatic penile cancer who are ineligible for or progressing on platinum-based chemotherapy, and the (NCT03774901), which is looking into the role of avelumab as maintenance therapy after PR or stable disease with first-line chemotherapy.

NCT03686332 is a phase II research that compares the use of atezolizumab with or without radiation in individuals with advanced penis SCC, characterized as inoperable disease that is either locally progressed or metastatic. NCT04224740 is another phase II trial. Recruitment of patients with advanced illness to be given pembrolizumab in addition to standard-of-care treatment chemotherapy.

Multiple combination strategies with ICI are also being tested.

10 Stage-Wise Treatment Algorithms

10.2 Stage 3 Nodal disease—cN1, cN2 (Fig. 8). Treatment of Primary as in Stage 1 and 2 Disease

10.3 Stage 4 Disease—N3, T4, and M1 (Fig. 9)

10.4 Management of Recurrent Disease Including Specific Palliative Measures

In all recurrences or suspected recurrences, a biopsy or FNAC, appropriate imaging and good patient counselling, is to be done. In recurrence post penile conservative excision, are excision to achieve tumor-free status is needed—either a partial or total penectomy. If initial partial amputation, a total might be needed. In case of locally inoperable recurrences, neoadjuvant chemotherapy and reassessment for intervention are needed.

Ilio inguinal LND done – Recurrence < 12 months
Ilio inguinal LND done – Recurrence > 12 months-
Ipsilateral ilioinguinal & contralateral modified Inguinal LND
Ipsilateral ilioinguinal & contralateral modified Inguinal LND
Ipsilateral ilioinguinal LND Observe contralateral groin
LND- Lymph node dissection

Fig. 10 Treatment algorithm for management of nodal recurrence

Nodal recurrences are managed as in Fig. 10. In case of systemic recurrences, follow algorithm of metastatic disease.

11 Stage-Wise Prognosis with Current Rx

As PeCa is uncommon, it is difficult to predict accurate survival rates of the cancer. The figures below regarding survival are from the National Cancer Institute's SEER database, analyzing more than 1000 men diagnosed with penile cancer between 1988 and 2001 [64].

- Stage 1 and 2 disease—5-year survival 85% with surgical management of primary (penile preserving and amputation surgeries). Recurrence rate with penile preserving surgery is 8.9% and with radiation therapy is 15%.
- Stage 3 disease—5-year survival is 59%.
- Stage 4 disease—5-year survival is around 11%.

Table 1 Recommendations for follow-up of the primary tumour

	Follow up interval		Examinations and investigations	Minimum period of follow-up
	Year 1–2	Year 3–5		
Penile-preserving treatment	3 months	6 months	• Physician or self-examination • Repeat biopsy after topical or laser treatment for penile intraepithelial neoplasia	5 years
Amputation	3 months	1 year	• Physician or self-examination	5 years

Table 2 Recommendations for follow-up of the inguinal lymph nodes

	Follow up Interval		Examinations and investigations	Minimum period of follow-up
	Year 1–2	Year 3–5		
Surveillance	3 months	6 months	• Physician or self-examination	5 years
pN0 at initial treatment	3 months	1 year	• Physician or self-examination • Optional: Ultrasound with fine-needle aspiration cytology	5 years
pN+ at initial treatment	3 months	6 months	• Physician or self-examination • Optional: Ultrasound with fine-needle aspiration cytology • Computed tomography/magnetic resonance imaging if indicated	5 years

11.1 Follow-Up

Rationale for follow-up is that early detection of recurrence increases the possibility for patient to undergo curative treatment because local recurrence does not affect long-term survival if successfully treated compared to distant recurrence, which is associated with reduced survival.

Follow-up schedule is based on the type of treatment like penile-preserving surgeries and amputation only or inguinal nodes were also addressed.

Tables 1 presents recommendations for follow-up of the primary tumor, and Table 2 presents recommendation for follow-up of the inguinal lymph nodes.

12 How We Do It at TMC (Table 3)

Table 3 How we do it at TMC

Diagnosis	Local examination	Biopsy of penile lesion (mandatory)	USG (b/l inguinal region and pelvis) In obese patient with low risk disease and for all clinical intermediate and high-risk disease *CT/MRI (abdomen and pelvis)* In selected patient in ≥ N2 disease, previous inguinal or pelvis surgery, obesity *Chest-X ray*	
Treatment	Stage 1 and 2	Penile-preserving approaches, partial or total penectomy	*Address lymph nodes:* Surveillance or prophylactic modified inguinal LND (based on risk stratification).	
	Stage 3	Partial or total penectomy	*Address lymph nodes:* Modified inguinal LND or Ilioinguinal LND	
	Stage 4	Partial or total penectomy Palliative penile surgery	*If operable post NACT*: Ilioinguinal LND *If inoperable post NACT:* Palliative chemotherapy	*In M1 disease,* palliative chemotherapy

LND lymph node dissection, *NACT* neoadjuvant chemotherapy

Testicular Cancer

Amit Joshi, Sameer Shrirangwar, Pritam Kataria,
Alok Goel, and Nikhil Pande

Abbreviations

BEP	Bleomycin, etoposide and cisplatin
CT	Computed tomography
EC	Embryonal carcinoma
GCNIS	Germ cell neoplasia in situ
GCT	Germ cell tumors
GEMOX	Gemcitabine and oxaliplatin
HDCASCT	High-dose chemotherapy and autologous stem cell transplant
IGCCCG	The International Germ Cell Cancer Collaborative Group
LDH	Lactate dehydrogenase
NSGCT	Nonseminomatous germ cell tumor
RPLND	Retroperitoneal lymph node dissection
SMN	Second malignant neoplasms
TNM	Tumor/node/metastasis
USG	Ultrasonography

1 Introduction

Testicular malignancies form a group of rare disorders with an incidence of 1% of all malignancies. Most of all testicular cancers are germ cell tumors (GCTs). The evolution of testicular cancer management is a milestone journey of success in oncology that merits highlighting. The 5-year relative survival is 97% from 2005 to 2011 [1]. However, this also results in many challenges in the management of GCT; the need of the hour is to prevent and mitigate overtreatment and exposure to unwarranted toxicities in patients with good-risk features and ensure an adequate treatment in patients with poor-risk features.

2 Incidence and Epidemiology

Testicular cancer is a very rare malignancy in the Indian context. India's incidence rates for testicular cancer rank among world lowest in the world (0.5 per 100,000 men) [2]. However, the incidence of this disease has been steadily increasing worldwide. In Northern Europe, specifically Norway and Denmark, the incidence of testicular cancers has more than doubled; approximately 1% of men are diagnosed with testicular cancer in their lifetime [3]. In the United States, the incidence has steadily increased over the previous two decades. The incidence of testicular malignancies is the highest among Caucasians and lowest among African Americans [4]. This increase in incidence has fortunately been met with remarkable strides in treatment and outcome, and consequently, the prognosis of testicular cancer is very favorable, mainly in high-income countries.

Risk factors for the development of testicular cancer are family history of testicular cancer (12-fold increased relative risk), cryptorchidism (4–6 time relative risk) and germ cell neoplasia *in situ* (GCNIS).

3 Histological Classification

The histological spectrum of GCTs comprises seminomatous and nonseminomatous (NSGCT) tumors. The types of NSGCT are embryonal carcinoma (EC), yolk sac tumor, teratoma and choriocarcinoma subtypes in pure forms or in various combinations as a mixed GCT, which in turn can also

contain seminomatous components thus composed of two or more GCT subtypes. For precursor lesions, newer terminology is used, viz., germ cell neoplasia *in situ* (GCNIS).

4 Clinical Presentation

Testicular swelling is often synonymous with testicular malignancies and is seen in approximately 75% of patients. Testicular pain is present in about 8–46% of GGCTs [5]. Acute pain is a feature of torsion or bleeding within the tumor. Other rare manifestations include gynecomastia seen in choriocarcinoma and back pain because of large retroperitoneal lymph nodes and can be detected during the evaluation of infertility.

Testicular masses are usually firm to hard with a normal scrotal sac—the other differential diagnosis of testicular mass is testicular torsion, varicocele, spermatocele and epididymitis.

Varicoceles are described as a "bag of worms" on palpation, and because of engorgement, the venous pampiniform plexus of the spermatic cord. Spermatoceles are found in posterosuperior aspects of the scrotum and trans-illuminate. Testicular cancer is commonly mistaken for epididymitis, marked by swollen and tender testicles. Hence, any patient of epididymitis who fails to respond to a 10-day course of antibiotics should be subjected to a thorough physical examination and evaluation with ultrasonography.

5 Evaluation and Work-Up

5.1 Testicular Ultrasonography

USG of testis differentiates testicular cancer from other entities. The differential diagnoses to be ruled out by USG are testicular torsion, varicocele, spermatocele and epididymitis, with testicular ultrasonography providing high sensitivity and specificity of differentiation and finality of diagnosis. Radiological observation of hypoechoic or heterogeneous lesions should prompt a stringent subsequent evaluation. Negative ultrasonography reliably rules out the presence of intrascrotal GCT [6].

5.2 Orchidectomy

Any patient with a suspected testicular mass clinical examination or testicular ultrasonography should undergo unilateral trans-inguinal orchiectomy with radical intent to rule out testicular carcinoma. Orchiectomy is the gold-standard definitive procedure for both logical diagnosis and local control and maybe a curative approach [7]. Orchidectomy may be delayed when control of metastatic diseases is needed urgently. Despite complete eradication of cancer from the viable metastatic deposits using systemic chemotherapy, orchiectomy is mandatory after completion of systemic chemotherapy to prevent relapse as there are chances of persistence of likely tumor within the testis owing to the presence of the blood-testis barrier [8].

5.3 Tumor Markers

Measuring pre and postorchidectomy levels of HCG, AFP and lactate dehydrogenase (LDH) is essential to stratify the disease exactly. Tumors are the fundamental component of the evaluation of testicular cancer patients and offer diagnostic, staging and prognostic information and help assess disease progression and response to therapy.

HCG is a glycoprotein of 45,000 MW. The half-life of serum hCG is 24 h. HCG consists of alpha and beta subunits. The beta subunit, measured in serum, is produced by the placenta at high levels in adults but low levels in normal nonpregnant adults. Beta hCG is produced by syncytiotrophoblastic cells mainly in choriocarcinomas and seminoma. Very high levels are usually associated with choriocarcinoma. Rarely in seminoma (in 5%–40%), beta hCG elevation can be seen but usually not exceeding 100 mIU/mL [9].

AFP is a protein with a half-life of AFP in serum of 5–7 days [10]. AFP is secreted physiologically in the fetal yolk sac, liver and gastrointestinal tract. The yolk sac component of the germ cell tumor mainly secretes AFP. Rarely embryonal carcinoma and teratoma can also secrets a small quantity of AFP. Patients diagnosed with seminoma and an elevated AFP are assumed to be nonseminomatous components and treated as per NSGCT protocol.

Lactate dehydrogenase (LDH) is another marker that is elevated in testicular tumors and is mainly found in muscle (including smooth, cardiac and striated), liver and brain tissues. Compared to β-hCG, LDH alone is less specific for diagnosing testicular cancer, with LDH-1 being most common and produced by the testis. The half-lives of this isoenzyme vary from 10 hours 3 to days. LDH is commonly used for prognostication of advanced disease in good-, intermediate- and high risk along with B-hCG and AFP [11].

5.4 Radiological Evaluation

Postorchidectomy radiological evaluation is mandatory to detect the spread of diseases in the retroperitoneum and lung. A CT imaging of the chest with the abdomen and pelvis is generally necessary. However, there is a slight controversy over the chest radiography against tomography, although most institutes consider CT scan thorax. It also helps compare the pulmonary nodules in response to therapy and subsequent follow-up.

5.5 Clinical Staging

Serum tumor markers and CT scans are the most used methods for detecting metastatic disease [12] in retroperitoneal adenopathy and lung metastasis. Contrast-enhanced CT scan is the preferred technique for detection. MRI brain is indicated in symptomatic patients and patients with high levels of beta -HCG levels. Similarly, a bone scan is indicated in a symptomatic patient.

5.6 Pathologic Staging

The staging classification of these primary tumors and the lymph nodes and is as follows:

(Table 1) [13] which can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no.732–733, Chapter

Table 1 Staging classification for testicular cancer

Tumor, node, metastases (TNM) staging in testicular cancers	
TNM category	Description
Primary tumor (T)	
pTx	Primary tumor cannot be assessed
pT0	No evidence of primary tumor
pTis	Intratubular germ cell neoplasia
pT1	Tumor limited to the testis and epididymis without vascular or lymphatic invasion. Tumor may invade into tunica albuginea but not tunica vaginalis
pT2	Tumor limited to the testis and epididymis with vascular invasion or tumor extending through the tunica albuginea with involvement of tunica vaginalis
pT3	Tumor invades the spermatic cord with or without vascular or lymphatic invasion
pT4	Tumor invades the scrotum with or without vascular or lymphatic invasion
Regional lymph nodes (N)	
Clinical	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass ≥2 cm in greatest dimension or multiple LN, none >2 cm in greatest dimension
N2	Metastasis with a lymph node mass >2 cm but not >5 cm or multiple LN, with any mass >2 cm but none >5 cm
N3	Metastasis with a LN mass >5 cm in greatest dimension
Pathological (pN)	
pNx	Regional LN cannot be assessed
pN0	No regional LN metastasis
pN1	Metastasis with a LN mass ≥2 cm in greatest dimension and ≤5 nodes positive
pN2	Metastasis with a LN mass >2 cm but not >5 cm in greatest dimension, or >5 nodes positive, with none >5 cm; or evidence of extra nodal extension of tumor
pN3	Metastasis with a LN mass >5 cm in greatest dimension
Distant metastases (M)	
M0	No distant metastasis
M1	Distant Metastasis
M1a	Nonregional node or pulmonary metastases
M1b	Distant metastasis other than to nonregional LN and lungs
Serum tumor markers (S)	
Sx	Marker study not available or not performed
S0	Marker study within normal limits
S1	LDH < 1.5 × N and hCG (mIU/mL) <5000 and AFP (ng/mL) <1000
S2	LDH 1.5–10 × N or hCG (mIU/mL) 5000–50,000 or AFP (ng/mL) 1000–10,000
S3	LDH > 10 × N or hCG (mIU/mL) >50,000 or AFP (ng/mL) >10,000

AJCC cancer staging system 2020

N normal limit, *LN* lymph node, *AFP* αfetoprotein, *hCG* human chorionic gonadotropin, *S* serum tumor markers

Table 2 International Germ Cell Cancer Collaborative Group (IGCCCG) risk nonseminoma seminoma

Stage grouping				
Group	T	N	M	S
Stage 0	pTis	N0	M0	S0

Measured after Orchidectomy. As per AJCC (2020)

no. 59, Testis, Table: Definition of TNM and Definition of Serum Markers (S), which can be accessed at https://emedicine.medscape.com/article/279007-workup#c7

5.7 Prognostic Value and Risk Stratification

Pretreatment (postorchidectomy) tumor marker levels (beta hCG, AFP, LDH) are valuable for staging and prognosis in men with testicular GCTs. Traditional tumor/node/metastasis (TNM) staging is not as proper a predictive tool as in other solid malignancies because the disseminated disease has a greater likelihood of long-term survival.

The International Germ Cell Cancer Collaborative Group (IGCCCG) now recommends serum tumor markers as a prognostic indicator in GCTs. In the IGCCCG schema, pretreatment (postorchidectomy) levels of serum beta hCG, AFP and LDH are independent predictors of risk, along with the site of primary disease and the presence of nonpulmonary visceral metastases [14]. The IGCCCG risk stratification system is described separately (Table 2).

6 Management of Clinical Stage I Disease

Almost every patient with clinical stage I germ cell tumors will survive. Stage I germ cell tumors have a cancer-specific survival of 98% to 99% [15]. Further, patients who have received adjuvant intervention have the same life expectancy as on observation. Hence, cost, the burden of the therapy and patient preference are the key guiding factors for treatment decisions.

Seminoma: Stage I seminoma is a joint presentation accounting for 70% of the disease burden. Risk stratification of Clinical stage I seminoma into high-risk and average risk is based on tumor size. Still, similar options exist for all patients with stage I seminoma, regardless of risk [15, 16]. Generally, they are diagnosed on the postorchiectomy specimen. The diagnosis of stage I seminoma is based on the following findings: histologic diagnosis of pure seminoma (without any evidence of nonseminomatous elements) on final pathologic analysis of the orchiectomy specimen. No pretreatment elevation of alpha-fetoprotein and no evidence of lymph node involvement or distant metastases based on staging computed tomography (CT) of the thorax, abdomen and pelvis (radiographer CT). Regular tumor marker studies following orchiectomy.

Eighty-five percent of the patients with stage I seminoma are cured by orchiectomy alone.

About 20% of the patient's risk of recurrence without any adjuvant therapy. Many retrospective studies have defined the risk of recurrence in these patients, i.e., tumor size more than 4 cm and invasion of rete testes [17, 18]. The treatment options for these patients include the following [17–19]:

- Orchiectomy followed by active surveillance.
- Orchiectomy followed by single-agent carboplatin.
- Orchiectomy followed by radiation therapy.

6.1 Surveillance

Approximately 15–20% of stage I seminoma will relapse if no further treatment is offered. The probability of recurrence in high-risk tumors more than 4 cm or with rete testis involvement is 30% to 35%, whereas patients with tumors less than 4 cm without rete testis involvement have a risk of only 12% [20]. Recurrences are temporally distributed over 10 years [21]. Retrospective series from the Royal Marsden Hospital London, from the Princess Margaret Hospital (PMH), Toronto, and from national collaboration in Denmark, have all concluded that surveillance is a reasonable policy [20].

Surveillance is a feasible option as these patients, if they recur, can have a similar cure rate by the salvage regimen compared to patients who receive radiation therapy or chemotherapy in an adjuvant setting. These patients, however, require periodic CT scanning as tumor markers are not elevated in Seminoma, and these patients usually recur in retroperitoneum.

Active surveillance is practiced to prevent the second malignancy as these patients are long-term survivors, and all do not require adjuvant therapy. Those patients who do recur can be salvaged safely.

6.2 Adjuvant Chemotherapy

Cisplatin-based combination chemotherapy is the backbone for treating advanced-stage testicular germ cell tumors. Carboplatin is often preferred in stage I seminoma because of its better toxicity profile. Carboplatin has better safety and toxicity profile than radiotherapy for stage one disease. In a noninferiority trial of carboplatin with radiotherapy enrolled 31,477 patients. They compared adjuvant para-aortic RT (para-aortic strip or dog-leg field and 20 or 30 Gy depending on the center) versus a single-cycle carboplatin CHT (area under the curve [AUC] of 7 mg/mL/min) [22]. This noninferiority trial established a comparable 3-year disease-free survival time between both arms (94.8 vs. 95.9%; $p = 0.32$) [23]. Both RT and carboplatin were well tolerated with different toxicity profiles. There were more frequent retroperitoneal recurrences after adjuvant carboplatin, so follow-up CT scans are mandatory. There were no reported instances of second malignant neoplasms (SMN) in patients treated with chemotherapy, and fewer contralateral germ cell tumors were reported compared to radiotherapy at medium-term follow-up.

The Current recommendation with carboplatin is to administer a single carboplatin dose that is appropriately dosed by renal scintigraphy for two cycles at three weekly intervals. There are no randomized trials of two cycles of carboplatin versus one process. Several phase II trials have shown benefits in reducing recurrences with two cycles of carboplatin; however, longer follow-up and a phase III study are needed to establish this approach.

Adjuvant Radiotherapy: A dose of 20 Gy to the para-aortic lymph nodes helps achieve excellent local control of nearly 100%. In the MRC trial, comparing 30 Gy with 20 Gy establishes equivalence in recurrence in both the arms [24]. Less toxicity in terms of infertility and other gastrointestinal effects is associated with the sparing of ipsilateral lymph nodes from the treatment field. For clinical stage I seminoma, the recurrence rate is as low as 4% after prophylactic radiotherapy, and the survival rates are significantly high with combination chemotherapy. Out of field recurrence in pelvic nodes and lungs can be seen occasionally. The contraindications for radiotherapy are patients with horseshoe kidney or inflammatory bowel disease. The ipsilateral scrotal contents and inguinal orchiectomy scar should be treated if a scrotal violation has occurred during surgery. After MRC publication, the 20 Gy dose option with a 2-week treatment time is the standard practice. Using this approach, the disease-free survival is close to 95%, and the long-term disease-specific survival rate is approximately 100% [25]. However, this approach is associated with an increased risk of second malignancies such as gastrointestinal and genitourinary [26]. With time, the use of prophylactic RT for stage I seminoma is declining gradually, and single-agent carboplatin is the preferred choice.

6.3 Pure Seminoma Stages IIA and IIB

Stage IIA and IIB pure seminoma comprise metastatic disease to lymph nodes measuring ≤2 cm (II A) and between 2 and 5 cm in size (II B). Patients with stage IIA and stage IIB seminomas can be treated with either RT or chemotherapy with three cycles of bleomycin, etoposide and cisplatin (BEP) or four cycles of etoposide and cisplatin (EP) [27]. Glaser et al., in a retrospective study, compared RT with multiagent chemotherapy in stage IIA–C seminoma patients. They concluded that 15-year OS was statistically higher in RT arm compared to chemotherapy arm, mainly in stage IIA patients (99% vs. 93%; HR, 0.28; 95% CI, 0.09–0.86; $P = 0.027$) [28]. Hence, the recommended treatment for Stage IIA disease is RT, while chemotherapy is the preferred therapy for Stage II B.

6.3.1 Follow-up for Pure Seminoma Stages IIA and Nonbulky IIB

After Primary Treatment

For stage IIA and nonbulky location IIB seminoma, the recommended follow-up schedule includes physical examination, history and serum tumor markers (AFP, beta HCG, LDH) post orchiectomy, which should be performed every 3 months during the first year and every 6 months from second to the fifth year. A chest x-ray is recommended every 6 months for the first 2 years. An abdominal CT scan with or without a pelvic CT scan is recommended for 3 months, 6 months and 12 months in the first year and then annually from the second to the fifth year. Unless clinically indicated beyond 5 years CT is not recommended.

6.4 Pure Seminoma Stages IIC and III

6.4.1 Primary Treatment for Pure Seminoma Stages IIC and III

Patients with stage IIC or stage III seminomas are classified as either excellent or intermediate risk based on the site of metastasis.

All stage IIC and stage III seminomas are considered good-risk diseases, except those with nonpulmonary visceral metastases (e.g., bone, liver, brain), which are regarded as an intermediate-risk diseases. The recommended treatment for patients with good-risk disease is three cycles of BEP or four cycles of EP [29, 30]. For patients with intermediate-risk disease, the recommended treatment is with four cycles of BEP or four cycles of etoposide, mesna, ifosfamide and cisplatin (VIP) [22, 31].

6.4.2 Immediate Follow-Up of Pure Seminoma Stages IIA, IIB, IIC and III

CT scan with contrast of chest, abdomen and pelvis with serum tumor markers (AFP, beta HCG) is recommended for patients with stages IIA, IIB, IIC and III seminoma after chemotherapy. Patients are then classified according to the presence and absence of residual disease in CT Scan. For patients with residual disease of more than 3 cm in CT scan, another investigation that has been recommended for evaluation of seminoma of patients is PET-CT, which should be done after 8 to 10 weeks of completion of chemotherapy [32, 33]. Surveillance is recommended if the PET scan is negative. If the PET scan is positive, the lesion must be resected/biopsied and subjected to histopathology examination. If the complete resection is done and HPE shows viable Seminoma then consider two cycles of EP or two cycles of other second-line regimen TIP (paclitaxel, ifosfamide, cisplatin), VIP or VIP (vinblastine, mesna, ifosfamide, cisplatin).

If the resection is incomplete and viable seminoma is present on HPE, then consider the course of second-line chemotherapy (4 cycles of TIP or four cycles of VIP or VeIP) [34]. If biopsy results are negative for viable seminoma, surveillance is recommended [35].

6.4.3 Follow-Up for Pure Seminoma Bulky Stage II and Stage III After Chemotherapy

Recommended follow-up schedule for patients with bulky stage II/stage III seminoma treated with chemotherapy consists of two monthly clinical examination and serum tumor marker assessment for the first year, the frequency of visit could be reduced to every 3 months in second year and further decreased to 6 months in third and fourth years and once in the fifth year. Beyond 5 years, CT imaging is recommended only when clinically indicated.

The patients also need to undergo thoracic imaging with an X-ray chest at a frequency of 2 monthly in the first year, 3 months in the second year and yearly through the third to fifth years.

6.5 Nonseminomatous Germ Cell Tumor

Management of clinical stage I NSGCT is divided and stratified as high risk and average risk. LVI has been validated as a risk factor because there are differences in the presentation of tumors including size, histology and tumor marker. NSGCT with LVI has been almost 50% of recurrence rate with observation. Within 2 to 3 years of orchiectomy, most relapses are expected. In "good-risk" stage I, the overall possible risk of relapse is approximately 30%, with patients with LVI-negative NSGCT having a chance of recurrence <30%. The risk of recurrence of stage I NSGCT with LVI negative with mainly embryonal carcinoma histology is higher than other NSGCT at 30% to 50%.

6.6 Surveillance

Retroperitoneal lymph nodes are a common site for relapse in patients on surveillance in approximately two-thirds of cases. Thee in the standards of one tone-third only show marker elevation alone without evidence of any focal site of relapse. Recurrences in nonpulmonary viscera are rare. Within 2–3 years of postorchidectomy, relapses occur; patients need follow-up for at least 5 years. Even those relapses, cisplatin-based chemotherapy has shown good results. Surveillance is not recommended for those who are anticipated to be poorly compliant. Observation is considered in most cases with the LVI-negative, clinical stage I NSGCT. There are no clear consensus on managing patients with pT2-pT4 tumors (including LVI-positive). Adjuvant chemotherapy I preferred treatment for LVI-positive or advanced T classification NSGCT; however, in patients with nonbulky (<5 cm) retroperitoneal disease and normal serum AFP and hCG levels and with the availability of experienced surgeon, RPLND can also be considered [34, 36].

6.7 RPLND

Retroperitoneum being the most common site for occult metastasis is targeted for disease control in the form of RPLND in patients with clinical stage I NSGCT without evidence of systemic disease. High cure rates have been observed in patients undergoing RPLND for occult retroperitoneal metastasis and teratoma. The lowest risk of abdominopelvic recurrence is observed when a complete bilateral template dissection is performed and high rates of antegrade ejaculation (>90%) are expected when nerve-sparing techniques are used. The least benefitted patients from RPLND are with stage IA embryonal carcinoma-predominant tumors, probably because of the tendency to spread via hematogenous route and thereby increase the risk of recurrence in lungs.

6.8 Adjuvant Chemotherapy

Bleomycin, etoposide and cisplatin (BEP) form backbone of primary chemotherapy. Several published studies are using either a single course or a double course of adjuvant BEP or clinically acceptable analogous regimens in patients with clinical stage I NSGCT [37]. The continuing risk of growing teratoma syndrome is an unwanted accompaniment to adjuvant chemotherapy and presents a limitation in adjuvant management. RPLND can only remove teratoma syndrome. By shortening treatment to one course BEP based over two, the toxicity of adjuvant chemotherapy is reduced.

This is based on encouraging results from various European trials, which showed recurrence rate of less than 5% with a single cycle of BEP with very few and acceptable toxicities and decreased rate of developing growing teratoma syndrome.

6.9 Stage IS

In Stage IS, serum tumor markers remain persistently elevated after radical orchiectomy with the absence metastatic disease and radiographic evidence of disease. Other causes of elevated levels of AFP and beta-HCG must be considered including hepatobiliary disease, marijuana use or hypogonadism. Clinically looking at pattern of tumor markers, may provide some clue regarding its etiology. Progressively rising markers may point to the malignant cause while stable markers point to the other cause than the malignancy. Elevated markers are generally in S1 markers range. Considering a disseminated disease in the absence of radiological site, the treatment is three courses of BEP or four courses of EP.

Management of Clinical Stage II: Metastasis limited to retroperitoneal lymph nodes is classified as Stage II GCT with S0 to S1 tumor markers. Most of these patients are cured with standard treatment as outlined below.

6.10 Clinical Stage IIA

Postorchiectomy serum AFP and beta-HCG levels are used as a cornerstone for guiding the response and treatment in patients with stage IIA NSGCT. Patients with normal postorchiectomy levels of AFP and beta-hCG can be treated with either chemotherapy with three cycles of BEP or four cycles of EP as primary treatment options or with nerve-sparing RPLND [38, 39]. Generally, for multifocal disease, chemotherapy is considered appropriate.

Management of nonseminoma Stage IIA: After Primary Treatment on the number of positive lymph nodes, treatment options following primary nerve-sparing RPLND are based. Patients with pN0 disease post-RPLND is surveillance. For the pN1 disease, the preferred choice is surveillance; however, chemotherapy with two cycles of BEP/ EP can be given. The recommended treatment for pN2 disease is two cycles of adjuvant chemotherapy with EP or BEP and full course of chemotherapy for pN3 disease (either three cycles of BEP or four cycles of EP) [40].

Tumor marker levels and the size of residual mass on CT scan dictate management after primary chemotherapy. CT abdominal/pelvic CT scans/chest CT with contrast is performed after completing chemotherapy to look for residual adenopathy. The nerve-sparing RPLND is recommended for patients with a residual mass ≥1 cm. For patents with normal tumor markers residual mass <1 cm surveillance is recommended.

6.11 Nonseminoma Stage IIB

Primary Treatment for Nonseminoma Stage IIB: Treatment for patients with stage IIB nonseminoma depends on postorchiectomy serological and radiological response. When postorchiectomy tumor marker levels respect normal ranges, the CT findings determine the proper course of treatment. If abnormal radiographic findings are limited to the lymphatic drainage sites within the retroperitoneum (i.e., the landing zone), primary chemotherapy with either three cycles of BEP or four cycles of EP must be given. RPLND as primary treatment must be reserved for highly selected cases. The outcomes are similar with both approaches but differ with respect to side effect profile. The documented relapse-free survival is 98% with either approach [41]. Either four cycles of EP or three cycles of BEP are recommended as first-line chemotherapy if metastatic disease (based on radiographic findings) lies outside the lymphatic drainage sites (i.e., multifocal lymph node metastases with aberrant lymphatic drainage sites. The recommended treatment for stage IIB nonseminoma patients with persistent marker elevation is primary chemotherapy with either three cycles of BEP or four cycles of EP.

6.12 Advanced Metastatic Nonseminoma

The management of the advanced metastatic nonseminoma are based on whether the tumor is good, intermediate or poor risk by IGCCCG risk classification [14]. The risk is determined based on primary site of the germ cell tumor, stage of the disease and the tumor markers done on cycle 1 day one of first-line chemotherapy [42].

6.13 Primary Treatment for Good-Risk Nonseminoma

Stages IS, IIA, IIB, IIC and IIIA diseases include in IGCCCG good-risk group. Treatment for good-risk GCT consist of either four cycles of EP or three cycles of BEP. By above regimen approximately 90% of patients are cured with good-risk disease [43].

6.14 Primary Treatment for Intermediate-Risk (Stage IIIB) Nonseminoma

The standard treatment for these patients is four cycles of BEP or four cycles of VIP who may not be a candidate for Bleomycin therapy [22, 44]. The cure rate for these patients is approximately 70% with the standard chemotherapy regimen of four cycles of BEP [45].

6.15 Primary Treatment for Poor-Risk (Stage IIIC) Nonseminoma

For poor-risk patients the standard chemotherapy regimen is four cycles of BEP or alternatively four cycles of VIP [46]. In these poor-risk patient, 20% and 30% of patients are not cured with conventional cisplatin-based chemotherapy and <50% experience a long-standing, durable, complete response to four cycles of BEP.

6.16 Management of Good-, Intermediate- and Poor-Risk Nonseminoma

CT scans with contrast of chest, abdomen and pelvis with measurement of tumor markers are indicated to assess treatment response after conclusion of primary chemotherapy. If the CT is suggestive of absence of any disease and tumor markers are normal the recommendation is to put the patient on surveillance. Surgical resection of masses is recommended, if CT scan means PR and the tumor markers are normalized. It is usually recommended to perform RPLND within 7 to 10 days of tumor marker measurement and within 4 weeks of CT scan. Post-RPLND/resection of the residual mass's histopathology is reviewed. If the histopathology examination shows only necrotic debris or mature teratoma surveillance is advised. If histopathology shows embryonal, yolk sac, choriocarcinoma or seminoma elements two cycles of chemotherapy (EP, VeIP, VIP or TIP) is given. Patients with persistently elevated AFP and beta-hCG levels and with an incomplete response to chemotherapy are treated with either close surveillance or surgical resection of residual masses.

6.17 Central Nervous System Metastases

CNS metastasis can occur in patients with germ cell tumor. However, unlike other malignancies, few patients with brain metastasis are also curable [47]. In case of asymptomatic brain metastasis can be initially managed by chemotherapy with good response to therapy. Craniotomy is required in those with active bleeding. Postchemotherapy cycles residual lesion can be treated with radiotherapy, i.e., either SBRT or whole brain radiotherapy. Sometimes, shortly after completion of chemotherapy, patients may present with brain as solitary site of recurrence. These patients can be treated with curative intent with surgery.

6.18 Choriocarcinoma Syndrome

Metastatic choriocarcinoma is characterized by the following key elements-

1. Very high serum hCG levels usually more than one lakh
2. Either as testicular mass or mediastinal primary
3. Can have extensive lung metastasis
4. Other nonpulmonary visceral sites (liver, brain)
5. Tumor hemorrhage via hemoptysis, hemoperitoneum or intracranial bleed)
6. Hyperthyroidism [48].

Patients with choriocarcinoma syndrome are at a risk of complication like hemorrhage and recurrent/refractory disease and can have high rate of complications and death. Early diagnosis and early instillation of treatment decreases the above said complication. Generally patient with high beta HCG levels are at the risk of hemorrhage specially in those with pulmonary metastasis, are treated with EP chemotherapy for 3 days in the first cycle to reduce the risk of complication. For the subsequent cycles 2BEP or an ifosfamide containing regimen is given. Chemotherapy can be started as soon as the diagnosis is made and orchidectomy should be performed between cycles when the patient has stabilized, or at the time of RPLND.

Mediastinal Nonseminomatous Germ Cell Tumor: The most common presentation in this extragonadal NSGCT is in the anterior mediastinum of an adult man. Mediastinal GCT risk is increased in patients with Klinefelter syndrome [49]. One of the proposed theories, for the causation of extragonadal NSGCT is the arrest of migration of germ cells along the urogenital ridge during embryogenesis. The cure rate of mediastinal GCT is lower than most testicular germ cell tumors. The estimated 3-year progression-free survival is being in the range of 48–54% [50].

The primary chemotherapy is four cycles of BEP with good lung function and four cycles of VIP in patients who can't tolerate bleomycin.

Mediastinal primary tumors have a high incidence of viable germ cell malignancy, teratoma and transformation to somatic malignancy in postchemotherapy resections, so surgical consolidation is essential.

7 Management of Recurrent Disease

Second-line Therapy: After receiving the first-line therapy those with recurrence or those who fail to have complete response to first-line therapy are eligible for the second-line therapy or salvage therapy. These patients divided into favorable or unfavorable prognostic groups based on prognostic factors [51]. Low levels of postorchiectomy AFP and beta-HCG, low-volume disease, complete response to first-line therapy and the presence of a testicular primary tumor constitute favorable prognostic factors. Unfavorable prognostic features comprise an incomplete response to first-line therapy, high levels of tumor markers, high-volume disease and the presence of an extratesticular primary tumor. The favorable or unfavorable prognostic factors decides the management in second-line setting which include chemotherapy which is divided into conventional-dose and high-dose chemotherapy. Chemotherapy regimen includes either TIP or VeIP as conventional-dose regimen and high-dose carboplatin plus etoposide or paclitaxel plus ifosfamide forms high-dose regimen followed by autologous stem cell transplant [52]. Patients with unfavorable prognostic factors are usually considered for high-dose regimens. For those with solitary site of disease like single CNS metastasis, surgical resection can be considered. Successful salvage is possible in 50% of cases in first recurrence after BEP chemotherapy. The relapse-free survival with high-dose chemotherapy and autologous stem cell transplant (HDCASCT) in one retrospective study was 60% and is an alternate attractive option. Late relapses (>2 years after completion of primary therapy) occur in 2–3% of testicular cancer survivors.

7.1 Post-Second-Line Therapy

As after the first-line therapy, those receiving second-line therapy must undergo contrast enhanced radiological response assessment of the chest, abdomen, pelvis via Computed Tomography and serological assessment by measurement of serum tumor markers. Those patients with complete radiological response and normal tumor markers can be placed on surveillance.

Surgical resection of all residual masses is recommended for those patients with a partial response to second-line therapy and normal marker levels, while those with an incomplete response and persistently elevated marker levels should be subjected to surgical resection of residual masses, if possible, followed by surveillance.

7.2 Palliative Therapy

The palliative chemotherapy options include combinations of gemcitabine with paclitaxel and/or oxaliplatin [53, 54]. Further, all patients with intensively pretreated, cisplatin-resistant or refractory disease should be considered for palliative therapy. Based on Phase II trials where we investigate efficacy and toxicity, gemcitabine and oxaliplatin are recommended in patients with refractory cisplatin. The recommendation for gemcitabine and oxaliplatin (GEMOX) is based on phase II studies investigating the efficacy and toxicity of GEMOX in patients with relapsed or cisplatin refractory GCTs which safety and efficacy in these group of patients [55]. Based on the various phase II trials for patients with unresectable disease or metastatic MSI-H or mismatched repair deficit (dMMR), PD1 antibody pembrolizumab has been recently approved by the FDA for patients. Pembrolizumab, a PD-1 antibody, has been recently approved by the FDA in patients with unresectable or metastatic MSI-H or mismatch repair-deficient (dMMR) solid tumors that have progressed following prior treatment and for those patients in which there are no other satisfactory alternative treatment options.

In the first phase II trial, Pembrolizumab showed activity in patients with nonseminoma GCTs who progressed after first-line cisplatin-based chemotherapy and at least one salvage regimen (high-dose or conventional-dose chemotherapy) [56]. The maximum response achieved was SD, and it was well tolerated. So larger phase III trials are required in metastatic refractory testicular cancers and are needed to fully assess the value of this therapy, especially in those with MSI-H/dMMR GCTs.

7.3 Retroperitoneal Lymph Node Dissection (RPLND)

RPLND provides critical staging information and is always to be performed with a curative intent. Either transabdominal or thoracoabdominal approaches are available for surgical exposure for RPLND Surgical Exposure for RPLND is achieved through either a transabdominal or thoracoabdominal approach. Supra hilar dissection has been replaced by RPLND template, this has proven to be a game-changer and has replaced the supra hilar dissection. It is now the standard against which therapeutic alternatives are judged. Template for bilateral standard infrahilar RPLND consist of bilateral ureter (laterally), renal hilum (superiorly), bifurcation of iliac vessels (distally). A bilateral infra hilar RPLND includes the precaval, retrocaval, paracaval, inter aortocaval, retroaortic, preaortic, para-aortic and common iliac lymph nodes bilaterally. To minimize the possibility of a late paracolic recurrence, the ipsilateral gonadal vessel must be completely excised. Template for modified right RPLND consist of ureter (laterally), midpoint of aorta (medially), bifurcation of iliac vessels (inferiorly). and renal hilum (superiorly). Template for modified left RPLND consist of ureter (laterally), midpoint of vena cava (medially), bifurcation of iliac vessels (distally) and renal hilum (superiorly). 5 Chances of successful ejaculation are maximized by Modified RPLND templates by limiting dissection in areas thought to be at reduced risk of metastatic spread based on surgical mapping studies. This approach minimizes contralateral dissection, thereby reducing trauma to the hypogastric plexus and contralateral postganglionic sympathetic fibers. In the primary or postchemotherapy setting, nerve-sparing techniques can be used. In a nerve-sparing RPLND, both sympathetic chains, the postganglionic sympathetic fibers and hypogastric plexus are prospectively identified, dissected and preserved. Antegrade ejaculation is preserved in over 95% of all patients with prospective nerve-sparing techniques, that is why actual value of templates to prevent ejaculatory function loss is reduced. Whatever the approach chosen by the surgeon, the preservation of the margins of resection remains the primary priority and must not be compromised to preserve ejaculation.

USPIO	Ultrasmall superparamagnetic iron oxide
VBT	Vaginal brachytherapy

1 Introduction

Endometrial cancer (EC) is the most common gynecological malignancy in the developed world and the second most common gynecological malignancy after cervical cancer in the developing world [1]. Majority of the patients (about 75%) present early with the disease being limited to the uterus and the cervix and about 68% percent of women at diagnosis have localized disease [2]. Surgical management forms the primary modality of treatment and adjuvant treatment in the form of radiotherapy or/and chemotherapy is required depending upon stage and risk factors.

2 Incidence

Endometrial cancer comprises 4.4% of all malignancies in females and ranks sixth in the order of cancers afflicting females. GLOBOCAN 2018 estimates 282,069 new cases of EC across the world accounting for 2.1% of all new cancer cases with an estimated mortality accounting for 0.9% of cancer-related deaths worldwide [1]. There is a varied incidence pattern across socioeconomic regions with an age standardized rate (ASR) of 11.1/100,000 women in High development index regions and ASR of 3.3/100,000 women in low/medium development index regions. Incidence in India is reported to be lower. As per the ICMR PBCR data, there is a significant geographical variation in the incidence of endometrial cancer across India also with Chennai topping the list with an ASR of 6/100,000 women and Manipur being the lowest with an ASR of 0.3/100,000 women [3].

3 Epidemiology

EC is a disease of the perimenopausal and post-menopausal age group and more than 90% cases occur in women older than 50 years of age. Median age at diagnosis is 63 years; however, EC occurs almost a decade earlier in Indian women

with median age at diagnosis of 54 years. Less than 5% of all cases may occur in young women aged less than 40 [4].

Endometrial cancers have traditionally been classified into two main clinicopathological and molecular types. Type I comprising endometrioid adenocarcinoma (80–90%) and Type II formed by the non-endometrioid histologies [5]. Type I EC are associated with genetic alteration in PTEN, KRAS, PIK3CA, MLH1 promoter hypermethylation, whereas type II are associated with TP53 mutations [6]. The Cancer Genome Atlas (TCGA) has now established four molecular subtypes: (1) POLE (ultramutated) tumors, (2) microsatellite unstable tumors, (3) copy number high tumors with mostly TP53 mutations, and (4) remaining group without these alterations [7].

4 Risk Factors

Type I endometrial cancers are commonly associated with prolonged estrogen exposure. Some of the factors responsible include estrogen replacement therapy, metabolic syndrome, chronic anovulation (polycystic ovarian disease), estrogen-producing tumors (granulosa/theca cell tumors of ovary), peripheral conversion of androgens to estrone in adipose tissue, and tamoxifen use. Women who are nulliparous, infertile or those who have early menarche or late menopause are also at an increased lifetime risk of developing EC. Metabolic syndrome has a relative risk of 1.89 for the causation of endometrial cancer with the strongest association being with obesity (RR-2.21).

Certain genetic disorders are also associated with a high risk for developing EC. Lynch syndrome or hereditary nonpolyposis colon cancer (HNPCC) is inherited in an autosomal dominant fashion which results in an increased risk of developing malignancies due to a defect in DNA mismatch repair. The risk of developing EC by 70 years of age is highest for a mutation in MLH1 (54%) followed by MSH2 (21%) and MSH6 (16%). Women with Lynch syndrome develop EC at a much younger age compared to the general population with median age at diagnosis being 46 years [8]. Women with Cowden syndrome (germline PTEN mutation) are at an increased risk for breast, thyroid, and endometrial cancers.

5 Clinical Presentation

EC classically present as abnormal uterine bleeding. EC is the cause of 15% of all cases of postmenopausal bleeding. EC should be excluded in all postmenopausal women with pyometra, perimenopausal women with menorrhagic cycles or intermenstrual bleeding, symptomatic premenopausal women with a prior history of PCOS, symptomatic post-menopausal women on tamoxifen or asymptomatic postmenopausal women with atypical glandular cells in pap smear. EC can also present as abnormal vaginal discharge or incidentally detected thickened endometrium in ultrasound examination performed for a different indication. In advanced stages with peritoneal disease, EC may present similar to advanced ovarian cancer like abdominal pain and distension.

6 Evaluation and Work-up

Basic evaluation starts with general physical examination including a detailed pelvic and abdomen examination. Women with a history of postmenopausal bleeding are usually evaluated initially with a transabdominal and a transvaginal ultrasound (TVS) which reveals endometrial thickening. The USG cut off for endometrial thickening is considered to be 5 mm. Data reviewed from 13 published studies accounting for nearly 2900 patients showed that the 5 mm cut off resulted in a high sensitivity and specificity of 90% and 54% respectively. If the cut off is lowered to 3 mm it offers only a slight increase in sensitivity (98%) while at the same time significantly compromising specificity (35%) [9].

Delineation of tumor margins on TVS can be difficult, especially when it is diffusely infiltrating the myometrium. The use of saline infusion (i.e., sonohysterography) increases the accuracy of TVS to 84–89% in evaluating deep myometrial invasion. There are reports though suggesting an increase in pelvic dissemination of disease on using saline infusion hysterography.

EC appears as a hypoattenuating and hypoenhancing mass in the endometrial cavity on contrast-enhanced computed tomography (CECT). However, this appearance is nonspecific, and the differential diagnosis includes submucosal leiomyomas, endometrial polyps, or cervical stenosis. CECT has a poor sensitivity and specificity for determining myometrial invasion ranging from 40 to 75% and is thus currently used mainly for evaluation of nodal involvement and metastatic disease [10] (Fig. 1).

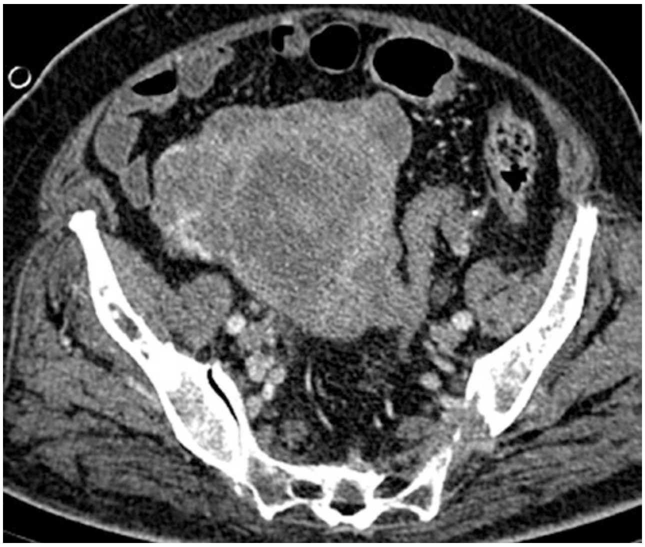

Fig. 1 CECT scan (axial section) uterine surface involved (Stage IIIA)

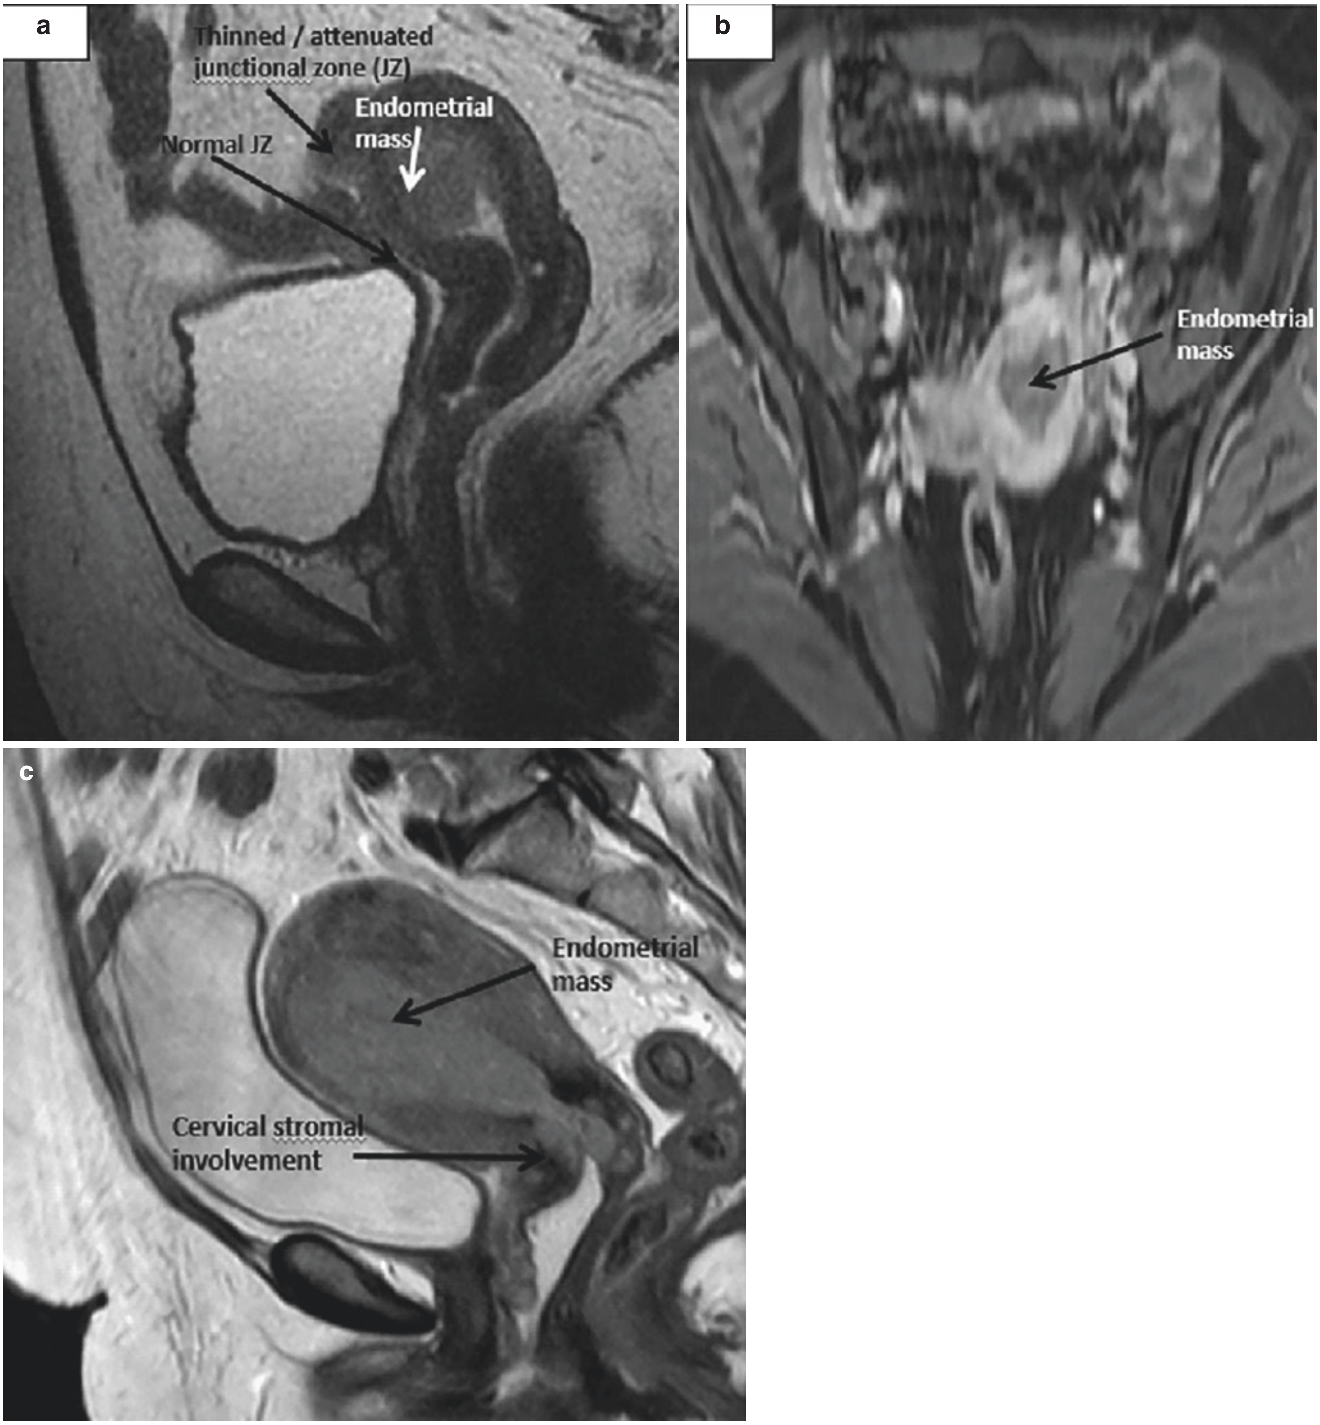
Magnetic resonance imaging (MRI), owing to its high spatial resolution, is the imaging modality of choice for local staging of EC with overall staging accuracy between 83 and 92%. On MRI, EC is usually seen as a hypo-to-isointense mass on T1-weighted images (T1WI) with an intermediate signal intensity on T2-weighted images (T2WI). On dynamic post-contrast images, EC is hypo enhancing. The sensitivity and specificity of MRI for identification of deep myometrial invasion are around 80% each, with a positive predictive value (PPV) of 86% [11] (Fig. 2). Functional MRI constitutes a profusion of sequences that allow for comprehensive biological assessment of a tumor and is emerging as a useful



a

Cervical stromal involvement

Fig. 2 (**a**) MRI-T2W sagittal section showing less than ½ of myometrial involvement. (**b**) Post contrast axial scan showing poor enhancement of the endometrial mass. (**c**) T2W sagittal section showing cervical involvement adjunct especially for the assessment of lymph nodal involvement. These modalities include (not limited to) MRI with ultra-small super paramagnetic iron oxide (USPIO) and diffusion-weighted (DW) imaging.

Positron emission tomography/computed tomography (PET/CT) is highly sensitive (51–69%) and specific (90–100%) for detecting lymph nodal involvement and distant metastases in selected high-risk patients with EC [12].

6.1 Genetic Counselling

Genetic risk assessment is recommended for patients with greater than approximately 20–25% chance of having an inherited predisposition to endometrial, colorectal, and related cancers. Revised Amsterdam criteria is most commonly used in patients with endometrial or colorectal cancers.

7 Staging (Table 1) [13]

7.1 Principles of Management

Comprehensive surgical staging for early-stage endometrial cancer includes peritoneal cytology, total hysterectomy with bilateral salpingooophorectomy with or without pelvic/para-aortic lymph node dissection followed by adjuvant radiotherapy with or without chemotherapy depending on the patient profile and histopathological parameters. Conservative management for fertility preservation may be adopted in young patients with early-stage cancer endometrium with proper counseling and strict follow-up protocols. Surgical staging can be accomplished by laparotomy or laparoscopy. Robotic surgery is an emerging minimally invasive treatment modality for cancer endometrium. The first joint ESMO-ESTRO-ESGO consensus conference on endometrial cancer and the working group has laid down recommendations for management of EC [14].

7.1.1 Fertility-Preserving Treatment

Approximately 4% of cancer endometrium present before 40 years of age. Younger patients present with an early stage favorable histology and have a better prognosis after treatment than their older counterparts.

As per the consensus conference recommendations [14], conservative management of endometrial cancer can be considered in young patient less than 40 years of age with atypical hyperplasia (AH)/endometrial intraepithelial neoplasia (EIN) which are premalignant conditions or stage IA grade 1 endometroid endometrial carcinoma (EEC) confined to the endometrium, at specialized centers. The patient should be counselled pretreatment that the intended treatment is not a standard modality, that she has to adhere to strict follow-up protocols and she may require hysterectomy anytime during treatment or follow-up with risks and benefits of the treatment modality explained. The endometrial biopsy sample should be collected preferably by dilation and curettage with or without hysteroscopy which is considered superior to pipelle in ascertaining grade. The biopsy samples should be examined by specialist gyneconcopathologist. Pretreatment MRI or USG by expert sonologist should be performed to exclude myometrial invasion and adnexal involvement. The medical treatment given is medroxyprogesterone acetate (400–600 mg/day) or megesterol acetate (160–320 mg/day). The response rates for EC are approximately 75%, and recurrence rate is 30–40% [15]. Some papers on LNG IUS and gonadotropin-releasing hor-

Table 1 FIGO 2009 staging (adapted from Pecorelli S. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. Int J Gynaecol Obstet. 2009 May;105(2):103–4. doi: 10.1016/j.ijgo.2009.02.012. Erratum in: Int J Gynaecol Obstet. 2010 Feb;108(2):176. PMID: 19367689.) [13]

Stage		pTNM	Definition
I			Tumor confined to the uterine corpus ,
	IA	pT1a	No or less than half myometrial invasion
	IB	pT1b	Invasion equal or more than half of the myometrium
II		pT2	Tumor invades cervical stroma but does not extend beyond uterus
III			Local and/or regional spread of the tumor .
	IIIA	pT3a	Tumor invades serosa of the uterus and/or adnexae
	IIIB	pT3b	Vaginal and/or parametrial involvement
	IIIC		Metastases to pelvic and/or para-aortic lymph nodes
	IIIC1	pN1	Positive pelvic nodes
	IIIC2	pN2	Positive pars-aortic nodes with or without positive pelvic nodes
IV .			Tumor invades bladder and/or bowel mucosa; distant metastases
	IVA	pT4	Tumor invasion bladder and/or bowel mucosa
	1VB	pM1	Distant metastases incl. intra-abd. metastases and/or inguinal nodes

mone (GRH) analogues have documented similar results and recurrence rates. The patient is followed up after 6 months with repeat dilation and curettage and endometrial biopsy along with imaging. If the results do not show any treatment response further conservative management is abandoned and hysterectomy is advised. If there is complete response, the patient is referred to infertility specialist. If she wants to postpone pregnancy, she is put on maintenance progestin treatment with 6 monthly follow up as advised. After completion of childbearing hysterectomy with salpingoophorectomy is advised. Ovaries can be preserved in young patients after exclusion of synchronous ovarian malignancy or ovarian metastasis or if she does not have a hereditary predisposition, but salpingectomy should be performed. Studies have shown ovarian preservation does not impact overall survival (OS) in young patients.

8 Surgical Management

The standard treatment is extra fascial total hysterectomy with bilateral salpingoophorectomy with or without lymph node dissection depending upon the frozen section findings. Surgery can be done by open technique, minimally invasive methods, or vaginal approach.

The largest randomized control trial GOG Study LAP2 compared laparoscopy vs laparotomy for comprehensive surgical staging of early stage (I – IIA) uterine cancer over a period of approximately 9 years [16]. Compared to 909 patients who underwent laparotomy, laparoscopy was initiated in 1682 patients and completed without conversion in 74.2% of patients [16]. The main conversion factors were poor visibility (14.6%), metastatic cancer (4.1%), bleeding (2.9%), and other causes (4.1%). Laparoscopy had significantly lesser moderate-to-severe postoperative adverse events but similar intraoperative complication rates. The median operative time was significantly higher in the laparoscopic arm (204 vs. 130 min), but the period of hospital stay was significantly lesser. Pelvic and paraaortic lymph node dissection was not carried out in 8% of patients in the laparoscopy arm as compared to 4% in the laparotomy arm which was statistically significant. Detection of metastatic disease was similar in both arms. So the authors concluded that laparoscopy is a safe and feasible option in terms of short-term outcomes, complication rates, and hospital stay in the management of EC. The major shortcoming appeared to be higher conversion rate owing to multicentric design and variable learning curve of surgeons. Long-term outcomes of the study were published in 2012 with a primary objective to establish noninferior recurrence-free interval with laparoscopy compared to laparotomy with a median follow-up of 59 months [17]. Though the estimated hazard ratio for laparoscopy was 1.14 (lower 90% confidence limit, 0.92; upper 95% confidence limit, 1.46) it fell short of protocol specified definition of noninferiority (lower bound of 1.0, upper bound of 1.4). The actual recurrences rates were lower than anticipated, with 3 years recurrence rates of 10.24% in the laparotomy arm compared to 11.39% in the laparoscopy arm and 5-year recurrence rates of 11.61% and 13.68% for laparotomy and laparoscopy, respectively. At the time of design of the study, with an expected recurrence rate of 15% with laparotomy, the acceptable upper limit of recurrence for laparoscopy was assumed 20.3% after 3 years. The 5-year OS was 89.8% in both arms. Thus, the authors concluded that apart from superiority in short term safety and length of hospital stay outcomes, the potential for increased cancer recurrence with laparoscopy is quantified to be small and can be reasonably useful in patient management of early stage uterine cancers with proper information. A meta-analysis of four RCTs by Palomba et al. [18] concluded no significant difference in OS, DFS, and cancer-related survival between laparoscopy and laparotomy though in the laparoscopic arm, longer operating times, lesser blood loss, and lesser rates of intraoperative complications was seen and there was no difference in pelvic/paraortic nodal yield. Significantly longer operative time but with low blood loss and low rates postoperative complications, similar intraoperative complications without any effect on pelvic/paraaortic nodal yield. Thus, laparoscopy can be regarded as a safe and effective management modality in early-stage EC. In patients who are not physically fit to undergo laparotomy or laparoscopy due to medical conditions or in certain low-risk EC which do not require lymphadenectomy, vaginal hysterectomy with bilateral salpingoophorectomy is an acceptable option. Alternatively, unfit patients can be treated by radiotherapy or hormone therapy.

Robotic surgery is an emerging minimally invasive modality and useful especially in obese patients.

8.1 Role of Lymphadenectomy

The role of lymphadenectomy has been a matter of debate over the past two decades. The crux of the matter is to characterize judicious lymph node dissection. Systematic lymphadenectomy has got its disadvantages and complications; however, it properly stages and prognosticates the disease and guides adjuvant management. Omitting lymphadenectomy understages the disease and subjects the patient to overtreatment with radiotherapy and chemotherapy.

There are various studies in the literature advocating for and against systematic lymph node dissection. Notable studies advocating against lymph node dissection in EC are A Study of Endometrial Cancer (ASTEC) [19] and the Italian study by Panici et al. [20]. Both of these studies concluded the lack of disease free or overall survival advantage by pelvic lymph node dissection in early-stage endometrial cancer. Though both of these were prospective randomized trials, they are criticized by the faulty trial designs and including low-risk endometrial cancers only. Lymph node yield in the ASTEC was low. The benefits of pelvic lymphadenectomy were not used to guide adjuvant treatment in either study. Systematic paraaortic lymph node dissection was not done in either of the trials. It should be emphasized that isolated paraaortic metastasis occurs to the extent of 12.5% Stage IB Grade II and 27% in Stage IB grade 3 disease, respectively. Several retrospective studies have demonstrated survival advantage of systematic pelvic and paraaortic lymph node dissection in intermediate and high-risk endometrial cancers. Notable is the SEPAL (survival effect of para-aortic lymphadenectomy in endometrial cancer). The results showed a significant longer OS in pelvic and paraaortic lymphadenectomy group than in pelvic lymphadenectomy alone in the intermediate- and high-risk group; however, OS was not related to lymphadenectomy in low-risk group [20].

The salient features related to systematic lymphadenectomy in EC as per the ESMO-ESTRO-ESGO Consensus conference recommendations can be summarized as follows:

If indicated, systematic lymphadenectomy includes pelvic and paraaortic lymph node dissection until the level of renal vein.

Systematic lymphadenectomy guides future adjuvant treatment.

Lymph node yield >10–11 is termed adequate.

Low-risk group—Stage IA grade 1/grade 2 endometroid cancers—Lymphadenectomy is not indicated.

Intermediate-risk group—Stage IA G3, IB Grade 1/grade 2 endometroid cancers—Lymphadenectomy may be considered as it helps in staging procedure though survival benefit has not been demonstrated.

High-risk group—Stage IB grade 3 endometroid cancers—Lymphadenectomy is indicated.

For nonendometroid histology apparent stage I disease, i.e., serous, clear cell, undifferentiated and carcinosarcoma, lymphadenectomy is indicated. Omentectomy is an additional staging procedure in serous cancers.

For incompletely staged high-risk cases, complete staging to be done prior to adjuvant treatment.

For stage II disease—Extrafascial hysterectomy with BSO with systematic lymphadenectomy is indicated.

(A Japanese study demonstrated no survival benefit with radical hysterectomy compared to simple hysterectomy in stage II EC. However, radicality may be adopted in individual circumstances to get free margins if parametria is involved.)

8.2 Role of Sentinel Lymph Node Mapping in EC

Sentinel lymph node is the first lymph node that is involved in the pathway of cancer metastasis via the lymphatic route. If the sentinel node is negative, it is surmised that the rest of the lymph nodes are not involved. Of the two studies, the SENTI ENDO study and the FIRES (Fluorescence Imaging for Robotic Endometrial Sentinel lymph node biopsy) trial [21], notable is the FIRES trial which was a prospective multicenter cohort study to evaluate the sensitivity and negative predictive value of sentinel lymph node mapping in stage 1 disease of all histologies undergoing robotic surgical staging as compared to complete lymphadenectomy which is the gold standard. Indocyanin green dye was injected into cervix (0.5 mg/mL) after anesthesia and sentinel lymph node was picked up by fluorescence imaging. The procedure has a sensitivity of 97.2% (95% CI 85.0–100) to detect node-positive disease with a negative predictive value of 99.6%. Thus, the authors concluded that the method has a high diagnostic accuracy in detection of lymph node metastasis.

For advanced stage ECs, multimodality treatment is preferred. The aim of surgery is comprehensive staging with optimal cytoreduction.

9 Pathology

Endometrioid adenocarcinoma is the most common histologic subtype comprising 75–80% of all ECs. Marked glandular proliferation with minimal intervening stroma is the typical histological appearance and resembles proliferative phase endometrium. Architectural grading is based on the amount of nonsquamous or solid component with grade I being formed by <5%, grade II ranging from 6 to 50% and grade III having more than 50% nonsquamous or solid growth pattern. Other histologic subtypes seen include uterine papillary serous, clear cell, mucinous, squamous cell carcinoma, transitional cell carcinoma, and mixed cell-type carcinoma.

9.1 Pathological Reporting

The Royal College of Pathologists has published guidelines for the pathological reporting of hysterectomy specimens for EC [21]. Core data items to be included in the report are

(a) Hysterectomy type
(b) Details of hysterectomy specimen—The different components of the specimen (uterine corpus, cervix, ovaries, and tubes) should be specified and macroscopic appearance recorded. The presence of a vaginal cuff and

of parametrial tissues should be recorded in case of radical hysterectomy specimens.

(c) Accompanying specimens—Omentum, if received, should be recorded. Number of lymph nodes from each site and peritoneal biopsies should be described.
(d) Gross tumor details—The gross appearance of the tumor including dimension, presence of gross myometrial invasion, cervical involvement, parametrial involvement, or serosal surface involvement
(e) Tumor type
(f) Tumor grade
(g) Depth of myometrial invasion
(h) LVSI
(i) Cervical stromal invasion
(j) Vaginal involvement
(k) Uterine serosal involvement
(l) Parametrial involvement
(m) Adnexal involvement
(n) Omental involvement
(o) LN involvement
(p) Peritoneal involvement
(q) Provisional FIGO stage

Non-core data items to be included are

(a) Specimen weight and measurements
(b) Location of tumor

10 Radiation Management

10.1 Risk Stratification

Multiple clinicopathologic factors have been evaluated based on which patients are divided into risk groups. Like most risk groupings across sites, this risk stratification also guides prognosis as well as the use of adjuvant therapy. Established prognostic factors include age, FIGO stage, depth of myometrial invasion, tumor differentiation grade, tumor type (endometrioid vs. serous and clear cell), and lymphovascular space invasion (LVSI). The latest risk stratification divides subgroups into low-risk, intermediate-risk, high-intermediate risk, and high-risk groups (Table 2) [14, 15].

The addition of molecular-based classification is particularly relevant as POLE mutant tumors are known to have an excellent prognosis, while p53 abnormal tumors have a poor prognosis. Another update in the risk stratification is the subdivision of LVSI into focal and substantial [15].

10.2 Low-Risk Endometrial Cancer

For patients with low-risk endometrial cancer, the risk of recurrence after surgery alone is less than 5%. Some patients which are considered as low risk as per the current risk stratification were previously included in randomized trials of adjuvant RT. There was no benefit of adjuvant RT for this subgroup. Another randomized trial by Sorbe et al. [22] for patients with low-risk EC (N = 645) treated with vaginal brachytherapy (VBT) also failed to show any benefit for the use of adjuvant brachytherapy. There have also been reports of increased toxicity, especially long-term gastrointestinal toxicity with the use of adjuvant radiotherapy (RT) without any benefit in terms of overall survival (OS) or reduction in distant metastases [23]. Therefore, patients with low-risk EC can be observed following surgery.

Table 2 ESMO-ESGO-ESTRO-ESP classification of risk groups for adjuvant therapy [14, 15]

Risk group	Molecular information	Histopathological features
Low risk	POLE mut	Stages I & II
Intermediate risk	MMRd/ NSMP	Stage IA, Low grade, LVSI −ve/ focal
High-intermediate risk	MMRd/ NSMP	Stage IB, Low grade, LVSI −ve/ focal
High risk	MMRd/ NSMP	Stage III–IVA with no residual disease Stage I–IVA Non EC with myometrial invasion
	p53 abn	St I-IVA with myometrial invasion (EC + Non EC) with no residual disease
Metastatic	Any molecular type	Gross residual disease

Stage I-II EC with POLE mutations have demonstrated excellent local control rates and do not require any adjuvant treatment. For stage III EC with POLE mutations, data is available from PORTEC-3 trial which showed excellent outcomes. However, since patients in both the arms received EBRT, the effect of omitting adjuvant treatment is difficult to quantify.

10.3 Intermediate-Risk Endometrial Cancer

Multiple randomized trials assessing the role of adjuvant RT in early-stage EC included patients who are currently classified as being in the intermediate-risk group. These trials (MRC ASTEC, PORTEC-1, NCIC CTG EN.5, GOG-99) [20, 24–26]) randomized patients after surgery (TAH + BSO) to either pelvic external beam radiation therapy (EBRT) or observation. All these trials and a meta-analysis [26] showed that EBRT reduced the risk of pelvic recurrence by threefold without any significant OS benefit. Lower pelvic recurrence rates, however, came at the cost of increase in GI toxicity. GOG-99 in contrast to PORTEC-1 mandated staging lymphadenectomy, emphasizing the role of EBRT even for node-negative disease. The reduced risk of recurrence in this case was mainly owing to reduction in vaginal recurrences.

Table 3 compares randomized trials of adjuvant RT with observation in early endometrial cancer.

Greatest benefit of RT was seen in a select subgroup of patients which forms the high-intermediate risk group. PORTEC-1 defined risk groups as age >60 years, >50% myometrial invasion and grade 3 differentiation, with the high-intermediate risk group having at least 2 of these characteristics. Patients in this subgroup who received adjuvant RT had a 5-year risk of locoregional recurrence (LRR) of 5% as compared to 20% for those who were observed. The risk of LRR was deemed high enough only in this subgroup for adjuvant RT to be considered.

The PORTEC-2 trial included only patients with the high-intermediate-risk factors defined in PORTEC-1 and randomly assigned patients to either adjuvant pelvic EBRT or VBT. There was no significant difference in the rates of vaginal recurrence (1.8% vs 1.6% for VBT and EBRT respectively, HR 0.78, 95% CI 0.17–3.49; $p = 0.74$) or pelvic recurrence (5.1% vs 2.1% for VBT and EBRT respectively, HR 2.08, 0.71–6.09; $p = 0.17$) between the two arms. Rates of acute GI toxicity were significantly lower with VBT as compared to EBRT with a better quality of life in favor of VBT [27].

LVSI and grade 3 differentiations have been identified as risk factors for disease recurrence by multiple studies, and these findings were confirmed in pooled analysis of PORTEC-1 and 2 which showed increased risk of nodal and distant recurrences in this subgroup of patients [28]. EBRT decreased the risk of regional nodal recurrence in this small subgroup (5%) of patients, while VBT did not.

The above stated studies were not adequately powered to show statistically significant OS benefit.

The pooled analysis of PORTEC 1 and 2 has enabled the development of nomograms which guide the assessment of risk and predict the benefit of adjuvant RT for patient subpopulations [29].

Data from the PORTEC-2 trial also showed that with VBT alone only a small number of patients had a higher risk of pelvic relapse based on substantial LVSI, p53abn, and L1CAM overexpression and hence only focal LVSI and no p53abn are included in intermediate-risk category.

In patients with intermediate-risk EC (stage I endometrioid, grade 1–2, >50% myometrial invasion, LVSI-negative), adjuvant VBT is recommended to decrease vaginal recurrence. If EBRT is considered, it should be delivered with small portals, restricted to the mini-pelvis. Patients need to be explained the potential risk of higher GI toxicity with EBRT. Observation is an option especially for patients younger than 60 years of age.

10.4 High-Intermediate-Risk Endometrial Cancer

The GOG 99 and PORTEC 1 trials reported a significant reduction in LRR from 26% to <6% and >20% to 5%, respectively; however, neither showed any difference in OS (both trials underpowered for OS end-point).

For this group of patients, the use of adjuvant RT, whether VBT or EBRT, is controversial. Various factors like intraoperative information, histopathological risk factors, and type of surgery are taken into account before making a decision. This notwithstanding, most older patients with tumor features of LVSI and high-grade differentiation tend to be treated with EBRT irrespective of lymph nodal dissection. Node-negative patients can be treated with mini-pelvic fields to avoid excess GI toxicity. VBT alone is sufficient for patients with deep myometrial invasion without LVSI. If LVSI is indeterminate, then it is better to err on the side of caution and treat with EBRT [30].

10.5 High-Risk Endometrial Cancer

High-risk endometrial cancer is a heterogeneous group formed by both endometrioid and nonendometrioid histologic subtypes and is associated with an increased risk of pelvic recurrence and distant metastases. It is also important to understand that the spectrum of patients in the high-risk group is wide in terms of the stage of disease ranging from IB Grade 3 to more advanced stages. Nonendometrioid tumor types have a high percentage of extrauterine disease at presentation (60–70%). Patients with uterine serous cancer have a 5 year OS of about 20–25% as compared to 80% for all patients with endometrial cancer.

The estimated 5-year OS is 85–90% for stage I, 75–85% for stage II, 50–65% for stage III, and 20–25% for stage IV [14].

Due to this overwhelming heterogeneity, separate recommendations have been made for the following subgroups:

Table 3 Comparison of randomized trials of adjuvant RT with observations in early endometrial cancer

	LN Dissection	VBT	LRR	OS
PORTEC-1	NO	NO	4%(RT) vs 14%(NAT), $p < 0.001$	81% vs 85%, $p = 0.31$
GOG 99	MANDATORY	VBT	3% (RT) vs 12% (NAT), $p = 0.007$	92% vs 86%, $p = 0.557$
ASTEC/EN.5	29% patients	Allowed	4% vs 7%	85% in both arms

Endometrioid stage I, grade 3 and >50% myometrial invasion; endometrioid stage II; endometrioid stage III without residual disease and nonendometrioid tumor types.

For high-risk patients, standard of treatment remains pelvic EBRT. Two randomized trials (NSGOEC-9501/EORTC-55991 and MaNGO ILIADE-III) were conducted to evaluate the role of sequential combination of chemotherapy and radiotherapy in high-risk EC.

Hogberg et al. published the pooled analysis of these two studies which reported that the addition of adjuvant chemotherapy (4 cycles of platinum-based chemotherapy given either before or after RT) to EBRT led to a significant improvement in 5-year progression-free survival (78% vs. 69%, $P = 0.009$) and a trend toward improved OS (82% vs 75%, $P = 0.07$). Subgroup analysis from the study showed that the benefit was seen only in endometrioid histology; however, owing to the unplanned nature of the analysis and the small sample size, no clear conclusions can be drawn for it [31].

The PORTEC-3 trial (adjuvant EBRT alone vs. EBRT with concurrent and adjuvant chemotherapy) reported a significant improvement in 5-year OS (81.4% vs. 76.1%; $p = 0.034$) and failure free survival (FFS) in favour of chemoradiotherapy (76.5% vs. 69.1%; $p = 0.016$) (2 cycles concurrent with radiation followed by 4 cycles of chemotherapy) as compared to pelvic radiotherapy alone. Subgroup analysis revealed that the benefit was significant in more advanced/aggressive disease with 11% FFS benefit and OS benefit in patients with stage III disease, non-endometrioid histology and patients older than 70 years of age. However, as expected, the addition of chemotherapy resulted in significantly higher grade 2 and above toxicities [32].

The GOG-258 trial compared the same chemotherapy-radiotherapy schedule used in PORTEC-3 with six cycles of carboplatin-paclitaxel chemotherapy alone and found overlapping relapse-free and overall survival rates. However, the chemotherapy alone arm had significantly higher rates of pelvic and peri-aortic nodal relapse.

Molecular analysis of PORTEC-3 trial showed statistically significant survival advantage for p53abn carcinomas with combined therapy for stages I–III. In contrast, *POLE*mut carcinomas had almost no recurrences in both arms. There was no clear benefit of added chemotherapy for MMRd, while the NSMP carcinomas had some benefit of added chemotherapy especially in case of stage III.

Adjuvant therapy for patients with high-risk node negative EC (stage I endometrioid, grade 3, >50% myometrial invasion, regardless of LVSI status) with adequate surgical nodal staging should include adjuvant EBRT with small portals. However, VBT may be considered as an alternative in select cases. For patients who have not undergone surgical nodal staging, pelvic EBRT should be given with or without adjuvant chemotherapy.

10.6 High-Risk, Stage II Endometrial Cancer

The definition of stage II was modified in the 2009 FIGO staging system. Endocervical glandular involvement was moved to stage I as it has no prognostic impact. A SEER analysis was carried out for stage II endometrial cancer patients in who almost half had cervical stromal involvement. This analysis did not show any difference in OS for the type of surgery that was performed in terms of radical or simple hysterectomy but RT independently of surgery was associated with survival benefit [33]. There is a lack of consensus as to the role of VBT boost in combination with EBRT. In case of positive vaginal margin, indication of VBT is clear. Studies have not found a clear difference in LR or OS rates for stage II patients treated with or without VBT in addition to EBRT.

In patients who are node negative upon a thorough surgical staging, EBRT with mini pelvic fields (with or without VBT boost) is recommended only for high-grade tumors or those with LVSI, while VBT is sufficient for lower grade without LVSI. For patients who have not undergone a thorough surgical nodal staging, pelvic EBRT with VBT boost is recommended with the addition of chemotherapy for high-grade tumors or those with LVSI.

10.7 High-Risk, Stage III Endometrial Cancer

Secord et al., in a retrospective analysis, showed that for patients with stage IIC endometrial cancer survival was worst in those who received adjuvant chemotherapy alone as compared to those who received either RT alone or combined RT and chemotherapy. Relapse-free survival was similar in patients receiving RT alone or in combination with chemotherapy [34]. Therefore, pelvic and/or extended field RT remains standard of care in this group of patients. In light of results of the trials already mentioned afore combined radiation therapy with chemotherapy is recommended as opposed to either alone.

In patients with high-risk, stage III endometrial cancer without residual disease, EBRT and chemotherapy in combination are recommended with extended field EBRT reserved for stage IIC2 disease.

10.8 High-Risk, Non-Endometrioid Cancers

These are rare tumors hence most studies are retrospective and comprise of small number of patients. A large retrospective study conducted by Viswanathan et al. suggested a survival benefit for the combination of chemotherapy and RT in uterine serous cancer [35]. However, as mentioned earlier, a subgroup analysis of the NSGOEC9501/EORTC 55991 and

MaNGO-ILIADE III trials did not show a survival benefit for serous or clear cell tumors. Since there is a high rate of distant metastases associated with these high-risk nonendometrioid histologies, adjuvant chemotherapy should be considered and clinical trials are encouraged.

Retrospective studies have investigated the role of VBT. One such study was conducted in patients of stage I serous or clear cell cancers. Of note, 34% patients included in the study also received adjuvant chemotherapy. The 5-year rate of isolated pelvic recurrence and LRR was 4% and 7%, respectively, with a 5-year OS rate of 84%, suggesting that VBT alone is sufficient in patients with stage IA disease [36].

Carcinosarcomas are rare and aggressive tumors with a large proportion of patients presenting with extrauterine disease at diagnosis. The 5-year OS for patients with stage I disease is a mere 50%. The EORTC-55874 trial randomized patients with stage I-II uterine sarcomas ($n = 224$) to either observation or pelvic RT (51 Gy/28 fr over 5 weeks) after surgery. About 40% of the patients on the study had carcinosarcoma. Adjuvant RT significantly reduced the risk of local relapse without any impact on OS or the rate of distant metastasis [37].

For all non-endometrioid histologies, adjuvant chemotherapy is recommended. For patients with serous and clear cell histology who have undergone thorough surgical staging, VBT alone is sufficient for selected early stage tumors (stage IA without LVSI). For stage IB or higher or patients with carcinosarcoma, pelvic EBRT should be considered.

11 Medical Management

The standard surgical management for EC leads to permanent loss of reproductive potential. A select group of patients in the reproductive age group and desirous of preserving fertility may be managed conservatively using oral progestins. Patients who are diagnosed with endometrial hyperplasia or FIGO stage IA Grade I endometrial cancer may be offered this approach. It is essential that MRI be used as part of the diagnostic work up to rule out deep myometrial invasion. The grade should be confirmed on D and C, and a mere office biopsy is not sufficient. The patients should be carefully selected and must be informed that this is nonstandard treatment, and they must be willing for close follow-up and may require to undergo hysterectomy in the future.

Medroxyprogesterone acetate (MPA) 40–600 mg/day or megesterol acetate 160–320 mg/day may be used. As an alternate, the use of LNG-IUD in addition to GnRh analogs has also been described, and the results in terms of response rates and recurrences are similar to that of oral progestins. Response is assessed at 6 months after therapy with repeat imaging and dilatation and curettage. About 75% of patients do respond, but there is also a high recurrence rate of 30–40%. If the patients respond, then maintenance therapy is continued for another 6 months otherwise patient is taken up for hysterectomy.

Chemotherapy is not recommended for patients in the low- or intermediate-risk group.

11.1 High-Intermediate Risk

The GOG 249 study investigated the role of chemotherapy in high-intermediate risk and high-risk patients. Patients were randomized to either pelvic EBRT or VBT followed by adjuvant chemotherapy (3 cycles of paclitaxel and carboplatin). The addition of chemotherapy did not result in improvement of either relapse-free survival or OS. In fact, there was a higher risk of pelvic and para-aortic nodal recurrence in the VBT and chemotherapy arm (9.2% vs. 4.4% at 5 years) [38].

11.2 High-Risk Patients

Many studies have attempted the addition of chemotherapy to RT or tried to substitute RT with chemotherapy for high-risk patients.

JGOG 2033 study randomized patients to pelvic EBRT vs. three cycles of adjuvant CAP chemotherapy (cyclophosphamide-adriamycin-cisplatin). The study found no difference in DFS and OS between the two arms [39].

As eluded to earlier, the pooled analysis of NSGOEC-9501/EORTC-55991 and MaNGO ILIADE-III showed a significant improvement in 5-year PFS and a trend to improvement in OS on addition of chemotherapy to RT.

The PORTEC-3 trial, as eluded to earlier, was initiated to evaluate the benefit of adjuvant chemotherapy during and after RT versus pelvic RT alone for women with high-risk EC. Patients with high-risk EC were randomized to receive RT alone versus concomitant chemoradiotherapy (two cycles cisplatin given during RT) followed by 4 cycles of carboplatin and paclitaxel. As seen with other studies, the combined chemotherapy and radiotherapy arm did not improve 5-year OS but showed an improvement in failure-free survival.

The GOG 258 trial in high-risk stage III / IVa disease compared adjuvant chemoradiotherapy and chemotherapy alone. Chemoradiotherapy consisted of 2 cycles of concomitant cisplatin with RT (intensity-modulated RT and VBT allowed) followed by 4 cycles of paclitaxel and carboplatin as opposed to 6 cycles of paclitaxel and carboplatin in the chemotherapy alone arm. The primary end point of the study, relapse-free survival showed no improvement with the addition of RT as compared to chemotherapy alone. In the chemotherapy alone arm, there were higher vaginal and nodal recurrences, whereas distant metastases were higher in the chemoradiotherapy arm [40].

For high-risk non-endometrioid histology, most of the evidence as mentioned is retrospective and small patient numbers. But in view of the high rate of distant metastases, chemotherapy is recommended in this subset of patients.

12 Advanced and Recurrent Disease

Surgery is preferable for patients with advanced (bulky IIIA/IV) or recurrent disease but should be performed only when complete cytoreduction without macroscopic residual disease can be achieved. Evidence from meta-analysis of 672 patients has shown patients who undergo complete cytoreduction [41]. Exenteration is also an option for patients with advanced disease and central relapse.

For early-stage endometrial cancers especially grade I/II without LVSI or deep myometrial invasion are amenable to observation. These patients may end up with isolated vaginal recurrences in which case salvage RT provides good local control. In PORTEC-1, patients with isolated vaginal relapses were treated with radical intent with a combination of pelvic EBRT and VBT with a resulting local control rate of 89% and 79% DFS at a median follow-up of 44 months. Patients who receive adjuvant primary RT are at an increased risk of distant relapses. In these patients, reirradiation may be considered especially with the advent of sophisticated techniques like image-guided intensity-modulated radiotherapy.

The benefit of addition of chemotherapy for patients with vaginal relapses or pelvic nodal recurrences is unclear. GOG 0238 is an ongoing trial that is randomizing patients to EBRT plus VBT versus EBRT boost with weekly cisplatin chemotherapy. The results of this trial should make the picture clearer but for the time being for the patients who are deemed to be at a high risk of systemic relapse, the addition of chemotherapy may be considered.

For patients who present with painful bony metastases or painful nodal recurrences or bleeding, palliative radiotherapy remains an option.

12.1 Systemic Therapy in Recurrent/Metastatic Disease

Thigpen et al. showed that hormone therapy is a viable option with a convenient toxicity profile in patients who have recurrent disease. Hormone therapy is more effective in Grade I/II tumors with response rates of 37% in grade I, 23% in grade II, and only 9% in grade III tumors [42]. For patients whose disease is not surgically resectable nor amenable to radiotherapy, hormonal therapy is a good first-line option if disease is not rapidly progressive. In case of rapidly progressive disease, systemic chemotherapy needs to be considered.

Clinical trials have shown that objective response rates are higher for combination of cisplatin and doxorubicin than doxorubicin alone. A GOG trial showed that the addition of paclitaxel to cisplatin and adriamycin (TAP regimen) significantly improved median PFS (8.3 mo vs. 5.3 mo) and OS (15.3 mo vs. 12.3 mo), but this improvement came along with an increase in the toxicity as well as a result of which the TAP regimen has not been adopted as a standard of care [43].

GOG 209 was a non-inferiority trial which randomized patients to receive TAP-based chemotherapy vs a combination of paclitaxel and carboplatin every 3 weeks. The PFS in the two treatment arms was similar and the TC arm had a non-inferior OS. The TC arm had a definite advantage in terms of toxicity profile and also TC can be administered on outpatient basis, whereas the TAP regimen is usually administered with the patient admitted [44]. As a result, TC has now been adopted as the regimen of choice for recurrent/metastatic disease. There are no randomized data for second-line chemotherapy, though.

Many newer targeted agents have also been evaluated of which the most promising seems to be bevacizumab. In the MITO-END 2 trial, bevacizumab was added to 6–8 cycles of TC followed by maintenance therapy significantly improved PFS (13 mo vs. 8.7 mo) [45].

1 Introduction

Cervical cancer continues to present as a challenge to gynecological oncologists considering large number of women who die annually of the disease. The presentation of cervical cancer differs in the developed and the developing world. Early stage disease constitutes 60% to 70% of patients in the developed world contrary to three-fourths presenting as locally advanced disease in low–middle-income/low-income countries (LMIC/LIC). The recent declining incidence of cervical cancer across the globe can be attributed to improving living standards and widespread screening strategies. This chapter briefly summarizes the management of cervical cancer from evaluation to treatment, highlighting the protocol followed at Tata Memorial Centre.

2 Incidence and Epidemiology

Cervical cancer is the fourth most common cancer among women worldwide with an estimated new case load of 569,847 and 311,365 deaths across the globe (GLOBOCAN 2018). In India, it is the second leading cause of female cancers after breast cancer with age standardized incidence rate of 14.7 per 100,000 women. Annually, India has new 96,922 cases with

60,078 cervical cancer deaths as estimated in 2018. The age-standardized mortality rate is 9.2 per 100,000 women per year in India as compared to the global rate of 6.9 [1].

3 Clinical Presentation

In an early stage, patients may be asymptomatic and cervical cancer discovered incidentally during screening. Postcoital bleeding is the most common presentation. Other presentations may include foul-smelling blood tinged discharge, intermenstrual bleeding or postmenopausal bleeding. In late advanced stages, pelvic pain, urinary and bowel symptoms related to invasion or obstruction may be present. In cases with distant metastases shortness of breath, headache, seizures and bone pain may present as per the organ of spread.

4 Evaluation and Work-Up

Complete physical and pelvic examination is a must for clinical evaluation and staging of patients presenting with cervical cancer. A directed punch biopsy is taken for confirmation of diagnosis. In a very small lesion or with negative biopsy in a highly suspected case, colposcopic-guided biopsy is appropriate. Pelvic examination should entail detailed per-speculum, per-vaginal and per-rectal examinations. In cases of doubtful parametrial involvement or a noncooperative patient, examination under anesthesia (EUA) is done. At present, no tumor markers have been proven to be useful for evaluation or during follow up in cases of cervical cancer. Chest X-ray is used for staging purposes. The imaging modalities that are used are an ultrasound scan, computed tomography (CT) and magnetic resonance imaging (MRI). In resource strained settings, a good sonogram with high resolution probe can suffice. Information via sonogram can be gathered by abdominal, transvaginal and transrectal approaches. T2-weighted MRI is the modality of choice as it is superior in demarcation of growth, parametrial involvement and extent of involvement when planning for trachelectomy [2]. For parametrial infiltration, EUA has shown to have a negative predictive value of 65.3% and MRI of 76.9%, respectively [3]. For staging purposes, MRI is superior as compared to CT scan (sensitivity 75% vs. 51%) [4]. Nodal involvement detection is almost similar with MRI and CT imaging (sensitivity 38%–89%; specificity 78%–99%) [5]. FDG-PET imaging seems to be superior in sensitivity, specificity and accuracy for pelvic, para-aortic nodal disease evaluation [6]. Suspicious pelvic or para-aortic nodes on CT or MRI should be confirmed with image-guided fine-needle aspiration cytology (FNAC) or biopsy. Cystoscopy or sigmoidoscopy can be used for cases with suspected bladder or rectal invasion, respectively. The updated FIGO 2018 staging of cervical cancer is given in Table 1 [7]. The revisions essentially include stage IA definitions changes, addition of stage IB3 and including pelvic/para-aortic nodal involvement as a part of staging.

Table 1 FIGO staging of carcinoma of the cervix uteri (2018)

Stage I			The carcinoma is strictly confined to the cervix uteri (extension to the corpus should be disregarded)
	IA		Invasive carcinoma that can be diagnosed only by microscopy, with maximum depth of invasion <5 mm[a]
		IA1	Measured stromal invasion <3 mm in depth
		IA2	Measured stromal invasion ≥3 mm and < 5 mm in depth
	IB		Invasive carcinoma with measured deepest invasion ≥5 mm (greater than stage IA), lesion limited to the cervix uteri[b]
		IB1	Invasive carcinoma ≥5 mm depth of stromal invasion and <2 cm in greatest dimension
		IB2	Invasive carcinoma ≥2 cm and <4 cm in greatest dimension
		IB3	Invasive carcinoma ≥ 4 cm in greatest dimension
Stage II			The carcinoma invades beyond the uterus, but has not extended onto the lower third of the vagina or to the pelvic wall
	IIA		Involvement limited to the upper two-thirds of the vagina without parametrial involvement
		IIA1	Invasive carcinoma <4 cm in greatest dimension
		IIA2	Invasive carcinoma ≥4 cm in greatest dimension
	IIB		With parametrial involvement but not up to the pelvic wall
Stage III			The carcinoma involves the lower third of the vagina and/or extends to the pelvic wall and/or causes hydronephrosis or nonfunctioning kidney and/or involves pelvic and/or para-aortic lymph nodes
	IIIA		Carcinoma involves the lower third of the vagina, with no extension to the pelvic wall
	IIIB		Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney (unless known to be due to another cause)
	IIIC		Involvement of pelvic and/or para-aortic lymph nodes, irrespective of tumor size and extent (with r and p notations)[c]
		IIIC1	Pelvic lymph node metastasis only
		IIIC2	Para-aortic lymph node metastasis
Stage IV			The carcinoma has extended beyond the true pelvis or has involved (biopsy-proven) the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to stage IV
	IVA		Spread of the growth to adjacent organs
	IVB		Spread to distant organs

Adapted from [7]

When in doubt, the lower staging should be assigned

[a] Imaging and pathology can be used, where available, to supplement clinical findings with respect to tumor size and extent, in all stages

[b] The involvement of vascular/lymphatic spaces does not change the staging. The lateral extent of the lesion is no longer considered

[c] Adding notation of r (imaging) and p (pathology) to indicate the findings that are used to allocate the case to Stage IIIC. Example: If imaging indicates pelvic lymph node metastasis, the stage allocation would be Stage IIIC1r, and if confirmed by pathologic findings, it would be Stage IIIC1p. The type of imaging modality or pathology technique used should always be documented

5 Pathology

The malignant tumors of the uterine cervix include carcinomas, malignant mesenchymal tumors, mixed carcinomas and mesenchymal tumors, melanomas, hematolymphoid malignancies, germ cell tumors and secondary tumors. The discussion restricted to common epithelial malignancies—carcinomas.

5.1 Squamous Carcinoma

Squamous cell carcinoma of the uterine cervix includes microinvasive and invasive variants that may have different biological behavior such as verrucous, papillary, transitional, lymphoepithelioma, etc.

Microinvasive squamous carcinoma is a squamous carcinoma with early stromal invasion. Microinvasive squamous carcinoma should not be diagnosed on cervical biopsy, and only be diagnosed on large loop electrocautery excision procedure (LEEP) specimen, where the extent of the tumor can be studied in entirety.

An invasive carcinoma composed of squamous cells of varying degree of differentiation. Nearly all cervical cancers are caused by persistent infections by high-risk/carcinogenic human papilloma viruses (HPV), and proportion of squamous histology is approximately 70%. Macroscopically, it may be predominantly exophytic or endophytic. Histology shows irregular, spiked islands, sheets with intervening stroma. Keratin may or may not be seen. Cervical intraepithelial neoplasia (CIN) may be found on its surface or at the edge of the invasive tumor front. Conventionally, a four-tier grading system (Broaders) or a three-tier grading system (well, moderately differentiated, poorly differentiated) is in use; but it has not been proven useful prognostically (Fig. 1i, ii). Only recently, a novel, highly prognostic grading system has been proposed based on tumor budding and cell nest size for squamous carcinoma cervix [8]. A variety of subtypes are described (basaloid, verrucous, warty, squamotransitional, papillary, spindle cell type, lymphoepithelioma, etc.).

Pooled data indicate that a maximum depth of 3 mm or less is associated with a risk of lymph node metastasis of <1%, and a risk of invasive recurrence of 0.9%, while depth of invasion of 3–5 mm is associated with an overall risk of lymph node metastasis of 2% and a recurrence rate of 4% [9].

5.2 Adenocarcinoma

The relative and real incidence of endocervical adenocarcinoma (EAC) has been increasing worldwide, with up to 20–25% of all invasive cervical carcinomas now being assigned to this category [10].

The current World Health Organization (WHO) classification of cervical tumors lists types of cervical adenocarci-

nomas as usual type of adenocarcinoma, mucinous adenocarcinoma (gastric, intestinal, signet ring type), villoglandular carcinoma, endometrioid carcinoma, clear cell carcinoma, serous carcinoma, adenocarcinoma mixed with neuroendocrine carcinoma, etc. (see Fig. 1iii, iv) [9].

Most mucinous adenocarcinomas are considered to be HPV-associated tumors, but gastric type mucinous adenocarcinomas of the cervix (GAC) are mostly non-HPV-associated. The later show distinct morphological features, gastric phenotype, are HPV DNA negative, are negative for P16 and are positive for MUC6.

Hence, recently, International Endocervical Adenocarcinoma Criteria and Classification (IECC) proposed and showed a reliable segregation of HPV-associated (HPVA) and non-HPV-associated (NHPVA) endocervical adenocarcinoma. The non-HPV-associated tumors include gastric type, endometrioid type, clear cell type, mesonephric type, serous type and invasive adenocarcinoma, NOS [11].

Distinction between HPVA and NHPVA is important given the difference in their pathogenesis and clinical behavior, e.g., the gastric type adenocarcinoma has significantly worse outcome [12].

5.3 Neuroendocrine Carcinomas

Neuroendocrine tumors of the cervix are rare tumors and comprise less than 2% of all invasive carcinomas [13].

In among NET, carcinoid tumors and atypical carcinoid tumors (equivalent to well-differentiated grade 1 and grade 2 NET, respectively) are extremely uncommon in cervix. High-grade neuroendocrine carcinoma (small cell type and large cell type) are well recognized and are aggressive tumors. They are to be suspected when a seemingly poorly differentiated squamous carcinoma starts showing trabeculae or rosettes (see Fig. 1iv). Just like their lung tumor counterparts, they do show crushing artifacts. They are treated with surgery but more often with chemotherapy involving platinum and etoposide.

5.4 Mesenchymal Tumors

These rare tumors that arise from the cervix include leiomyosarcoma, endometrial stromal sarcoma, undifferentiated endocervical sarcoma, embryonal rhabdomyosarcoma, alveolar soft part sarcoma, angiosarcoma, malignant peripheral nerve sheath tumors.

6 Principles of Management

Patients with cervical cancer should ideally be managed in a cancer center with comprehensive cancer care services, which has the required expertise, skills and infrastructure. The primary prevention, screening and management of noninvasive and early micro-invasive cervical cancer (up to FIGO stage IA2) will be dealt in detail and out of scope of the current chapter. The treatment decision for invasive cervical cancer is based on (1) tumor-related factors including staging, histology type, and (2) patient-related factors including age, performance status, comorbidities and most important patient choice if options available. In general, early stage cervical cancers (FIGO stage I–IIA) are treated with radical surgery. Postsurgery based on adverse histopathological features, patients are classified in low, intermediate and high risk to offer adjuvant radio(chemo)therapy. Figure 2 shows the flowchart for diagnosis, evaluation and management principles for cervical cancer utilized at Tata Memorial Centre.

In early invasive cervical cancer (FIGO 2018 stage IB1 and IIA1) the standard of care is either surgery (radical/modified radical hysterectomy) or radiotherapy both of which have equivalent outcomes. However, combination of surgery and radiation in early stages does not improve outcomes in terms of local control rates or survival but definitely increases the treatment-related toxicities. Hence, proper patient selection and single radical treatment are associated with excellent outcome. This is possible in current era with the use of advancements in imaging modalities like MRI to identify adverse features like early parametrial involvement, depth of stromal invasion, significant uterine segment invasion and better selection for single modality treatment. Patients in whom need of postoperative adjuvant radiation is anticipated, chemoradiation should be preferred over surgery, as surgery followed by adjuvant radiotherapy is associated with significantly higher morbidity such as hydroureteronephrosis, intestinal obstruction and lower limb edema, compared to radical radiotherapy (28% vs. 12%) [14].

Nevertheless, in patients undergoing surgery, the decision regarding adjuvant therapy is a risk-adapted approach based on the final histopathology report and adverse features, including tumor size, vaginal cuff, parametrial dissection, number of nodes dissected, histopathological type, grade, vaginal and parametrial cut margins, depth of stromal infiltration, presence or absence of lymphovascular space invasion (LVSI) and nodal involvement. Patients planned for radical surgery, lymph node assessment intraoperatively and

frozen section evaluation if feasible and abandoning the primary surgery to offer chemoradiation may be useful.

Postsurgery, patients are deemed high risk if any one of the following features is present: lymph node metastases, positive surgical margins or positive parametrial extension. Adjuvant chemoradiation with external pelvic radiation therapy and concurrent weekly cisplatin chemotherapy are recommended [15]. In intermediate-risk patients as defined by the Sedlis criteria, in the absence of the high-risk features mentioned above and the presence of any two factors on final histopathology, namely, deep cervical stromal invasion, presence of LVSI or tumor size >4 cm, adjuvant pelvic radiation alone is recommended [16]. Low-risk patients are defined as having an absence of both high- and intermediate-risk features and require no further adjuvant.

Adjuvant radiation is delivered as external beam radiation therapy (EBRT) (preferably with intensity-modulated radiation therapy [IMRT] to reduce small bowel and hematological toxicity) to the pelvis to a dose of 45–50 Gy. A brachytherapy boost to the vaginal cuff may be added in patients at a high risk of local recurrence—close/positive surgical margins, simple hysterectomy with inadequate vaginal cut margins, parametrial or vaginal involvement, extensive LVSI and large tumor size. Alternatively, patients can also be offered definitive chemoradiation.

Patients with advanced stages (FIGO IIB–IIIB and select IVA) treated with radical chemoradiation including brachytherapy. Patients with advanced disease and not suitable of radical chemoradiation or metastatic disease are treated with palliative chemotherapy or radiation or both. In these patients it is important to incorporate palliative care early in the management to alleviate symptoms and improve QOL. The outcome of patients with relapse after definitive surgery with/without adjuvant therapy or chemoradiation is dismal. Salvage surgery for pelvic recurrences or chemoradiation for limited recurrences postsurgery is useful in only select group of patients and requires careful multidisciplinary discussion. Targeted therapy, especially with bevacizumab, has shown promising results with a median overall survival benefit of 4 months.

7 Surgical Management

The spectrum of surgery varies from radical trachelectomy to radical hysterectomy depending on stage and fertility desires of the patient. Early stage cervical cancers refer to cancers from FIGO stage I to stage IIA. The modalities of surgery and concurrent chemoradiation are equally effective in treatment of early stage disease. In small volume disease (size </=2 cm) and especially young sexually active females, surgery is advantageous. The advantages mainly include preservation of ovarian function and avoidance of radiation toxicities mainly vaginal stenosis. Although controversies exist in the management of bulky tumors (size >4 cm), surgery is still a viable option but should be done at a high-volume center with required expertise. Radical hysterectomy can be approached via open, laparoscopic or robotic surgery. However, recent evidence doesn't support the use of minimally invasive approach for radical hysterectomy [17–19]. At our institute, we proceed with bilateral pelvic lymphadenectomy at start and sending the nodes for frozen section. If the nodes are involved, procedure is abandoned and the patient is referred for concurrent chemoradiation. This approach helps prevent dual added morbidity of surgery and radiation. Radical hysterectomy is traditionally classified as suggested by Piver–Rutledge classification. In 2008, Querleu–Morrow classification based on fixed anatomical landmarks has been proposed. This classification has gained acceptance as it is also applicable for minimally invasive approaches and fertility-conserving surgeries. Both the classifications have been enlisted below [20, 21]. Nerve-sparing radical hysterectomy is an approach that avoids damage to the hypogastric and pelvic splanchnic nerves [22]. This helps avoid bladder, rectal and sexual dysfunction. However, at present, there is no level I evidence to prove its oncological safety.

7.1 Piver–Rutledge Classification (1974)

- Type 1: Extrafascial hysterectomy; removal of all cervical tissue
- Type 2: Modified radical hysterectomy; removal of medial half of the cardinal and uterosacral ligaments; the uterine vessels are divided medially to the ureter at the point of crossing of ureter
- Type 3: Classical Wertheim–Meigs operation; wide radical resection of the parametrium and paravaginal tissues with ligation of uterine vessels at the origin; ureter dissected completely to bladder entry; uterosacral ligaments divided at sacral attachment; cardinal ligament is divided at pelvic side-wall
- Type 4: Ureter is divided from pubovesical ligament; superior vesical artery ligated and upper two third of the vagina excised
- Type 5: Exenteration/extended radical hysterectomy with possible bowel, bladder or ureteric excision

7.2 Querleu–Morrow Classification (2008)

Type A:

- Minimum resection of paracervix, which is similar to extrafascial hysterectomy. The paracervix is transected medial to the ureter but lateral to the cervix.

Type B:
Transection of the paracervix at the ureter

- Partial resection of the uterosacral and vesicouterine ligaments, transection of the paracervix at the level of the Wertheim's tunnel.
- Type B1: without removal of paracervical lymph nodes
- Type B2: additional removal of paracervical lymph nodes

Type C:
Transection of paracervix at the boundary with internal iliac vessels

- Transection of the uterosacral ligament at the sacrum and vesicouterine ligament at the bladder.
- Type C1: with nerve preservation
- Type C2: without preservation of nerves

Type D:

- Laterally extended resection/exenterative procedures

7.3 Fertility-Conserving Surgeries

Radical trachelectomy and excisional conization are the surgical modalities used as fertility conserving approach for management of cervical cancer. Excisional conization can be considered appropriate for FIGO stage IA1 tumors without LVSI. The tissue is sent for frozen section and negative margins are to be confirmed. For tumors including FIGO stage IA1 with LVSI, IA2 and IB1 with preferred tumor size <2 cm, trachelectomy is the procedure of choice. It is to be emphasized that fertility-conserving approaches are not standard of care; these are deviations proven oncologically safe when the fertility desires of the patient are to be respected. Trachelectomy can be approached by either of vaginal, abdominal, laparoscopic or robotic route. Bilateral pelvic lymphadenectomy is done at the start of procedure, and the nodal tissue is sent for frozen section. It is proceeded once the report is negative for metastases. The criteria for selection of the patients who can be offered a fertility-conserving approach are listed below.

Criteria for fertility-conserving approach:

1. Strong desire for fertility preservation
2. Histopathology report of squamous carcinoma or adenocarcinoma
3. FIGO stage </=IB1 with preferable tumor size <2 cm
4. No evidence of nodal or distant metastases
5. Strong will for follow-up

8 Radiation and Medical Management

Patients with cervical cancer who are offered curative radio (chemo) therapy should always receive a combination of EBRT and brachytherapy (BT) with or with radiosensitizing platin-based chemotherapy [23].

8.1 External Beam Radiation Therapy (EBRT)

The main principle of EBRT for cervical cancer is to treat the primary tumor at cervix, gross nodal disease and the surrounding tissues with potential areas of spread (cervix uterus, parametria, upper vagina and ovaries—only in case of adenocarcinoma histology) and the draining regional pelvic lymph nodes (obturator, internal, external and common iliac, presacral). Typically, a dose of 45–50 Gy in 25 to 28 fractions with 5 fractions per week for 5 weeks is given to achieve optimal shrinkage of primary tumor to make it amenable for brachytherapy and to eradicate the microscopic disease in the other tissues. Patients suitable for concomitant chemoradiation will also receive weekly chemotherapy (detailed in next section). In case of pelvic lymph node involvement, EBRT may include the para-aortic region up to the renal vessels (45 Gy). In case of para-aortic lymph node involvement, EBRT volume includes the para-aortic region. Patients with gross nodal disease may be considered for additional doses as sequential or simultaneous radiation boost techniques.

Conventional/conformal pelvic box field (anterior–posterior and bilateral portals) techniques should be the minimum standards of EBRT as shown in Fig. 3. Newer radiation delivery techniques like IMRT, VMAT, etc. may also be used alternatively in experienced centers only. IGRT along with newer radiation techniques is highly recommended.

Typically, EBRT is delivered with the patient lying in the supine position with arms overhead/over the chest to keep them away from the radiation beam. A knee rest is placed below the knees to straighten the spine and fix the pelvis.

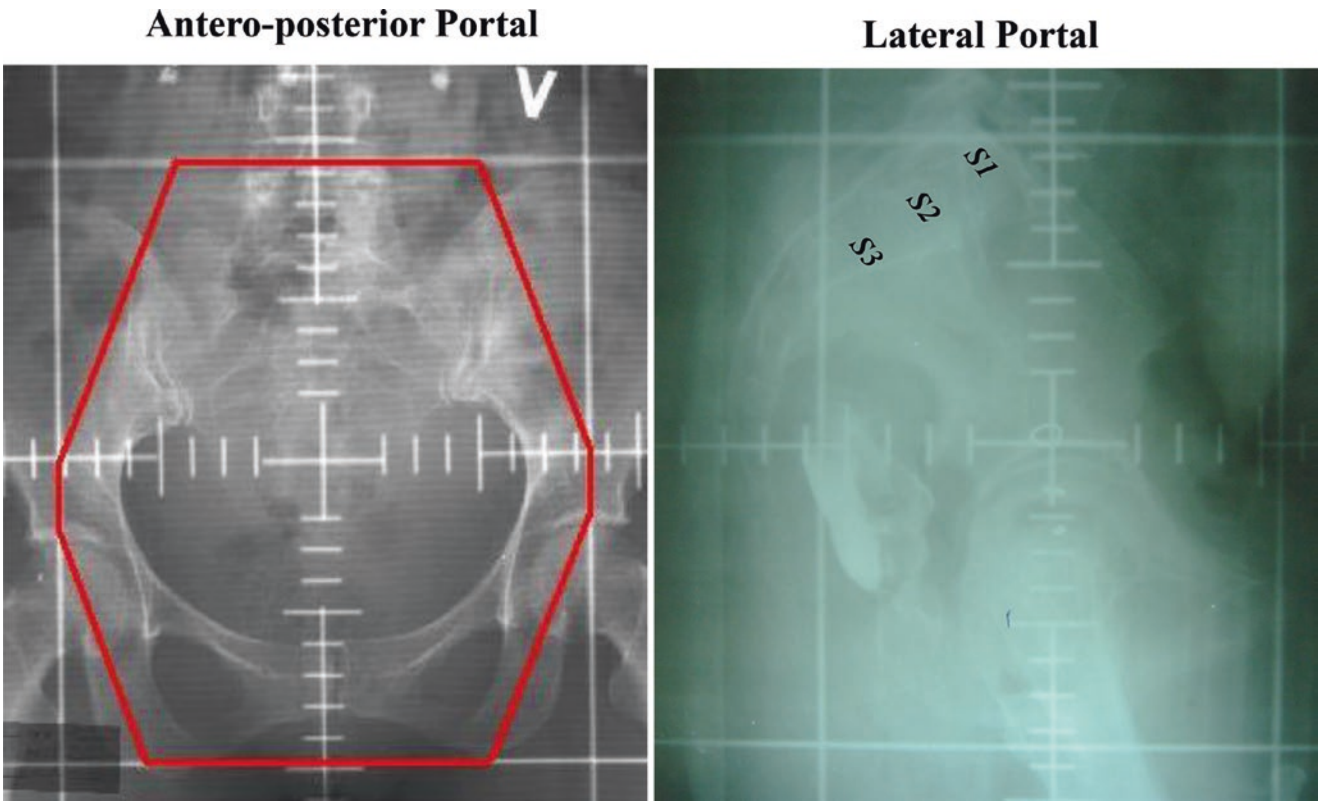

Fig. 3 Conventional EBRT techniques for cervical cancer external beam radiation therapy—two field or four field box techniques

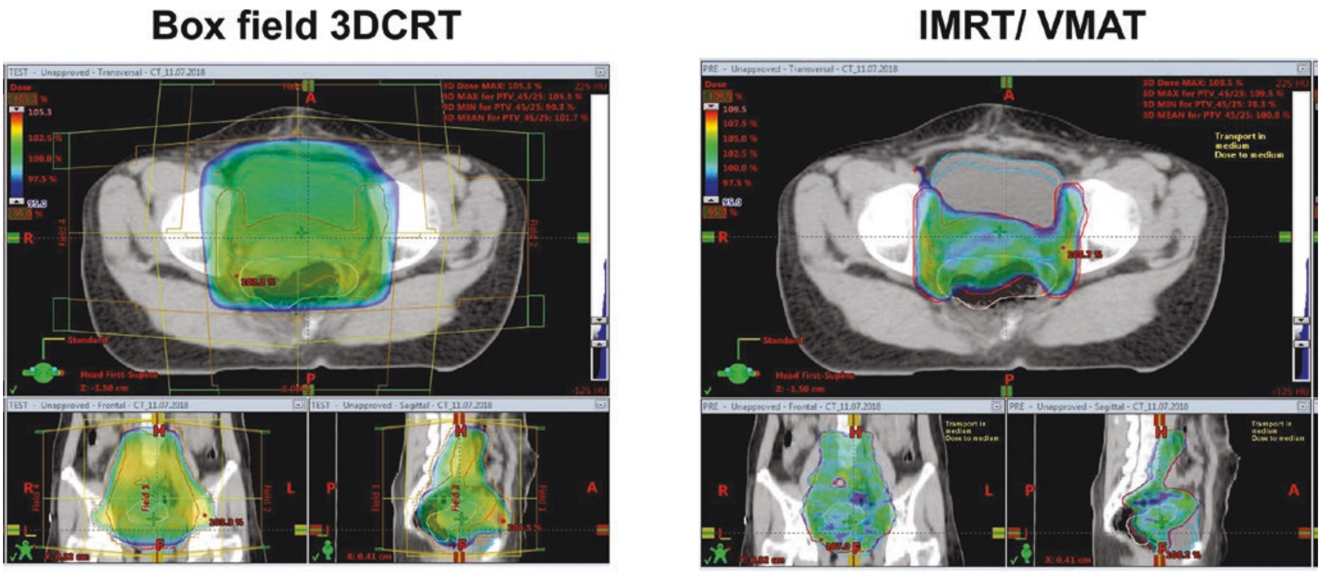
Patients are treated with a comfortably full bladder using a bladder-filling protocol so that the small bowel is displaced out of the pelvic region as much as possible and to ensure reproducibility during the entire treatment. In conventional treatment planning, the radiation field borders are fixed corresponding to the bony landmarks of the patients, as seen on the simulator X-ray. A box field technique is usually used for the pelvis (see Fig. 3), where four radiation beams—anteroposterior, posteroanterior and two lateral beams—are used for treatment delivery. The superior border of the AP-PA fields is placed at the L4–L5 interspace to adequately cover the common iliac nodes, inferior border is placed 2 cm below the gross tumor in the vagina, which is marked with a radio-opaque marker during simulation. The lateral borders are placed 1.5–2 cm beyond the widest part of the pelvic brim. The superio-inferior borders of the lateral fields are same as those of the AP-PA fields, the anterior border is placed at the anterior edge of the pubic symphysis, and the posterior border at the junction of S2–S3 vertebrae. The three-dimensional conformal radiation (3D CRT) involves the use of MLCs (multileaf collimators) for shaping the radiation fields to the target volume. The advantage of CT images is the identification of the metastatic lymph nodes and adaptation of the target volumes accordingly for, for example, the lower para-aortic nodal region. Intensity-modulated radiation therapy (IMRT) and volumetric arc therapy (VMAT) are newer technologies for radiation delivery and are useful to minimize the doses to normal structures without compromise in the doses to the target. Figure 4 shows the isodose color wash comparison of 3D CRT versus IMRT for cervical cancer. These delivery techniques have been utilized in the treatment of cervical cancer and are particularly useful in the postoperative setting as the small bowel falls into the pelvis and is within the radiation portal in hysterectomized patients. These newer techniques have shown significant reduction in high-dose regions to neighboring structures dosimetrically; however, there is a lack of robust clinical evidence [24]. The use of newer radiation delivery techniques in definitive settings (intact cervix) is challenging due to organ motion (cervix, uterus and bladder/rectal volume reproducibility) and tumor regression during the course of treatment which introduces lot of uncertainties in daily treatment. To minimize the uncertainties, image guidance (IGRT) during radiation has been utilized and protocol needs to be institutionalized [24].

Nevertheless, use of newer RT techniques has been utilized for the following:

- *Prophylactic extended field radiation*: With increasing stage risk of para-aortic lymph nodes, involvement increases and would benefit with prophylactic treatment. Conventional treatments with 2D have been long criticized for increased bone marrow and bowel toxicity. But with IMRT, the doses of 50 Gy can be safely delivered to these regions [25, 26].
- *Treatment of para-aortic nodal region and pelvic/para-aortic nodal boost:* These regions may include pelvic or para-aortic lymph nodes. Patients with significant nodal burden in the low para-aortic or up to renal hilum have been treated with newer RT techniques with dose escalation up to 60–65 Gy for better control rates with acceptable toxicities [25, 26].



- High doses to OARs is significantly lower without compromising high doses to the target

Fig. 4 Newer conformal EBRT techniques. Three-dimensional conformal radiation (3D CRT) versus intensity-modulated radiation therapy (IMRT) or volumetric arc radiation therapy (VMAT)

- *Stereotactic radiotherapy and oligometastases*: The incidence of oligometastases (OLM) in cervical cancer accounts less than 10% and could be synchronous or metachronous. In case of synchronous OLM with primary disease, the outcomes of lymph nodal involvement beyond the regional lymphatics (mediastinal and left supraclavicular) are better as compared to visceral metastases [27]. In patients with metachronous OLM, the outcome is favorable provided there is no local disease. The mainstay of treatment is systemic therapy, with doublet chemotherapy; the addition of bevacizumab has shown modest improvement in overall survival in a recent study. In the recent past, high-dose radiation (in the form of stereotactic body radiotherapy (SBRT) and or brachytherapy to the primary site) with or without chemotherapy has been explored with encouraging results. In a multi-institutional analysis of SBRT in the above group of patients, the authors reported 3-year progression-free survival of 33% and median overall survival of 32 months, which is much higher than the use of systemic chemotherapy alone, which is less than a year [28].

8.2 Brachytherapy (BT)

BT is usually planned toward the end of EBRT typically fifth week onward and plays a very important role in obtaining high cure rates with minimum complications. Typically, BT delivers very high doses of radiation to the residual primary tumor and adjacent high-risk areas with optimal sparing of neighboring organs/tissues namely bladder, rectum, sigmoid and/or bowel. The principles of BT include, BT application, imaging, planning and treatment. The brachytherapy application is done under anesthesia/sedation—bi-digital pelvic examination is mandatory to assess residual disease, identification and sounding of uterine canal (assisted by ultrasonography, if available), insertion of BT applicator assembly which consists of a straight tube in uterine canal called tandem, and a vaginal component placed in the lateral fornices, either in the form of a ring or two ovoids, which are usually perpendicular to axis of tandem, followed by vaginal packing to stabilize the applicator assembly. Imaging (orthogonal X-rays or CT/MRI) of the pelvic region is done. Figure 3 illustrates different types of brachytherapy applicators currently available for cervical cancer brachytherapy. Treatment planning is performed by medical physicist. The steps involved in planning include identification and reconstruction of applicator channels, source loading, defining patient/applicator-related points (point "A," ICRU bladder and rectal points) dosimetry, plan evaluation and finalization. BT treatment delivery is done using BT machine (commonly HDR BT).The radioactive source (Ir192/Co60) is introduced into the applicator via a remote after-loading machine, thus causing minimal exposure to the radiation personnel. BT is usually delivered in several fractions (3–4 fractions) with high-dose rate (HDR) or 1 to 2 fractions of pulse dose rate (PDR) [29].

8.3 Recent Advances in Cervical Brachytherapy

Conventional BT planning and treatment has been orthogonal radiography with Point "A" and ICRU 38 recommendations. The major limitation of the conventional imaging modalities is applicator and point based and there is a lack of information on the tumor volumes and organs at risk (OAR). In the last two decades, significant technological advances have resulted in use of newer imaging modalities like MR, CT, CT/MR-compatible applicators, better planning algorithms and treatment delivery. This has resulted in use of imaging techniques for three-dimensional data acquisition, defining residual disease, target, and various organs and optimize treatment planning Among the imaging modalities, MR imaging is becoming increasingly popular for diagnosis and treatment planning for EBRT and brachytherapy and has been established as gold standard for management of cervical cancer especially in developed world [30, 31].

MR image-guided adaptive BT (IGABT) processes has been established by GEC-ESTRO and the latest ICRU 89 report describes in detail [30–32]. The highlights include use of repetitive cross-sectional imaging including at BT with applicators in place, definition of various targets related to residual disease (GTV, HR-CTV, IR-CTV), planning and plan optimization to the target and prescribing/reporting of dose volume parameters in relation to the target and organs as detailed in Fig. 5. The outcome published from many mono-institutional series and preliminary results from multicentric retrospective and prospective studies indicate excellent local control rates of 95%–100% at 3/5 years in limited/favorable (IB/IIB) and 85–90% in large/poor response (IIB/III/IV) groups with acceptable treatment-related morbidity rates so far. Compared to the historical conventional BT series there is relative reduction in pelvic recurrence and reduction in major morbidity [33, 34].

Other imaging modalities like ultrasonography (US), CT scan or combinations as alternatives for IGABT are also being explored now. The CT has also been compared with MRI in few small dosimetric studies and need validation in larger clinical studies [35, 36].

8.4 Combined EBRT and BT Doses

With combination of EBRT and BT radiation, the overall aim is to deliver a tumoricidal doses of at least 75–80 Gy equivalent doses (EQD2) to point "A" or at least 85 Gy to the resid-

ual primary disease after EBRT for all stages. The overall treatment time (OTT) for completion of the entire course of radiation therapy EBRT and BT should be within 7–8 weeks, with delay beyond this time frame resulting in compromise in local control rates [37].

8.5 Side Effects Related to Radiation Therapy

Acute toxicities during pelvic radiotherapy are very common. Most patients experience mild to moderate fatigue, diarrhea, increased frequency & dysuria. The symptoms are more pronounced in 4th–fifth weeks of EBRT. Supportive and symptomatic treatment in the form of antidiarrheal medications, alkylating agents and hydration provide adequate relief of symptoms. The acute side effects are more pronounced when combined with weekly radiosensitizing chemotherapy or extended filed radiation therapy. In addition, hematological and renal toxicities are seen in patients receiving concurrent chemotherapy especially with Cisplatin/carboplatin [38].

The late toxicities after combined EBRT and BT commonly seen are rectal, bladder, small bowel and vagina. The clinical spectrum of late effects depend on the estimated radiation doses to the organs, type of treatment modalities, follow-up duration and disease-free interval. Typically, grade III/IV late sequelae (toxicities requiring hospital admission or intervention) are reported between 18 and 36 months posttreatment period but can appear as early as 6–9 months also and range between 5% and 15% and are seen any time after 6 months posttreatment period commonly between 18 and 36 months.

The clinical spectrum of late rectal toxicities include, tenesmus, telangiectasia, profuse painless bleeding, ulceration, rectovaginal fistula and strictures in 5–8%; late bladder toxicities, in the form of continuous painless hematuria, necrosis and rarely vesicovaginal or urethra-vaginal fistula (4%–8%); and small bowel late toxicities, including chronic enteritis, subacute intestinal obstruction, perforation and strictures in 3–12%, have been reported. The principles of management of late radiation toxicities are conservative except in severe life threating situations. Sucralfate enema, steroid enema, argon plasma coagulation (APC), laser therapy, or formalin applied to affected mucosa, diversion colostomy for rectal toxicities, hyperbaric oxygen therapy for hematuria and conservative or surgical intervention for small bowel late toxicities have been tried.

Lastly, telangiectasia, atrophy and fibrosis of the vagina, resulting in significant vaginal shortening, especially in elderly, postmenopausal women and those with extensive tumors treated with high doses of radiation is seen. These, to a large extent, can be prevented by early intervention in the form of vaginal dilatation exercises and counseling for regular sexual activity.

8.6 Concurrent Chemoradiation

The rationale of using concurrent chemotherapy with radiation is to increase the local tumor control by enhancing radiation action using radiosensitizing effects of various chemotherapeutic drugs, which would translate into better survival. Cisplatin is the most effective chemotherapeutic drug in treating cervical cancer. It acts synergistically with radiation by binding to DNA and causing inter- and intra-strand cross-links; it prevents repair of DNA damage caused by radiation. Cisplatin is nephrotoxic, ototoxic and myelosuppressive. It must be administered with adequate hydration and periodic monitoring of blood counts, renal function and audiometry. For cervical cancer, cisplatin is administered weekly, at 40 mg/m^2, and ideally an hour before a radiation fraction. Dose modification is required in patients with impaired renal function. Multiple randomized phase III trials comparing concurrent chemotherapy with radiation to RT alone, and their meta-analysis have shown an absolute benefit in disease-free and overall, with chemoradiotherapy in patients with stage IB2 to IVA disease as well as high-risk patients after hysterectomy [39]. A recent trial from our country exclusively included patients with III B cervical cancer, demonstrated an absolute benefit in DFS of 8.5% and OS of 6% at 5 years with addition of chemotherapy [40]. This reiterates the benefit of chemotherapy in our patient population, a larger number of who present with more advanced disease and were earlier thought to be poor candidates for concurrent chemotherapy due to poor nutritional/performance parameters as a result of poor socioeconomic status. Thus, concomitant chemoradiotherapy is the standard of care for locally advanced cervical cancer, with cisplatin being the chemotherapeutic agent of choice.

8.7 Neoadjuvant Chemotherapy in Cervical Cancers

8.7.1 Neoadjuvant Chemotherapy and Surgery

Several randomized trials and a meta-analysis of neoadjuvant chemotherapy followed by surgery versus surgery have been reported in FIGO Stage IB–IIB and have not shown any improvement in clinical outcomes. However, in the recent past, two large randomized trials (NCT00039338, NCT00193739) have been reported: one from Tata Memorial Hospital has reported inferior disease outcomes, while the final results of EORTC study are awaited [41].

8.7.2 Neoadjuvant and Adjuvant Chemotherapy and Radiation Therapy/Chemoradiation

In locally advanced disease, meta-analyses evaluating several randomized trials of neoadjuvant chemotherapy followed by radiation therapy have also reported negative results for outcome as compared to radiation alone [42]. However, subset analyses have shown that dose-dense and dose-intense chemotherapy had some benefit. Moreover, comparison with concurrent chemoradiation is lacking in the literature and is a subject of clinical research. A large randomized multicentric trial is ongoing (INTERLACE study—NCT01566240) to test improvement in survival after dose-dense paclitaxel-carboplatin neoadjuvant chemotherapy prior to radiochemotherapy versus radiochemotherapy.

Other aggressive treatment approach after completion of radical chemoradiation is to treat occult spread especially in locally advanced cervical cancers. One large randomized trial evaluated the role of thrice weekly cisplatin (50 mg/m^2) and gemcitabine for two cycles after chemoradiation reported significant acute grade III/IV hematological toxicities and moderate improvement in survivals, but this is practically difficult to implement in clinical practice out-of-trial settings, especially in LMIC/LICs. There are ongoing randomized trials (NCT00980954, NCT00141608), evaluating the role of paclitaxel—cisplatin or paclitaxel—carboplatin (Outback trial) adjuvant chemotherapy after chemoradiation.

8.8 Systemic Therapy

Patients with metastatic disease at presentation and recurrent disseminated disease are not curable and the intent of treatment is palliation of symptoms and prolongation of survival. Palliative chemotherapy especially combination chemotherapy regimens have generally been shown to improve response rates (RR) and progression-free survival (PFS) but not overall survival (OS) compared to single-agent cisplatin [43]. Most commonly used regimen is paclitaxel and either cisplatin or carboplatin [44, 45]. Carboplatin is preferred over cisplatin due to ease administration and better tolerability in terms of emesis, renal toxicities, ototoxicities, etc. Although there is no randomized phase III evidence for carboplatin, but there are several retrospective analyses and prospective nonrandomized studies that indicate equivalent efficacy. Carboplatin is substituted for cisplatin in many regimens by most clinicians. Another regimen that has been tested in a randomized phase III trial is topotecan plus cisplatin that was shown to be superior to single agent cisplatin with respect to RR, PFS and OS [46]. However, it is not usually preferred regimen due to its unfavorable toxicity profile, including myelosuppression and gastrointestinal toxicity. A recent phase III trial compared 4 platinum doublets (cisplatin + either of the following: paclitaxel, topotecan, gemcitabine and topotecan). There were no statistically significant differences in OS but there was a trend to superiority of cisplatin-paclitaxel in RR, PFS and OS [47]. Other agents uncommonly used as second line palliative chemotherapy include vinorelbine, irinotecan, ifosfamide and 5-FU. In patients in whom peripheral neuropathy is a concern, gemcitabine-platinum is an acceptable alternative. Carboplatin is substituted for cisplatin in many regimens by most clinicians. Generally, four to six cycles of chemotherapy are used.

In the recent past, several targeted therapies including bevacizumab have been tried. Use of bevacizumab in combination with other chemotherapy regimens has recently shown an absolute improvement in median overall survival by 4 months in patients with recurrent, metastatic cervical cancer [48].

8.9 Palliative Treatment

All patients should be registered for integrated palliative care approach, early in the course of metastatic and recurrent disease. Counseling and symptom control are some of the important components. Apart from general medications for symptom control including analgesics (especially opioids), prokinetics, effective palliation of symptoms due to disease (local, bone & brain metastasis, enlarged nodal disease) can be tackled with local radiation therapy. Palliative radiotherapy regimens typically range from 1 to 10 treatments delivered over 1–2 weeks. Palliative chemotherapy is generally used because there is some evidence that it may palliate symptoms and/or prolong survival in this setting**.** However, patients with poor performance status are not candidates for palliative chemotherapy, in general. Lastly, patients also benefit for best supportive care.

9 Cervical Cancer and Pregnancy

Every patient diagnosed with cervical cancer in pregnancy should be reviewed in multidisciplinary tumor board clinic including an Obstetrician and preferably managed at a tertiary cancer care center. With the wide-spectrum of treatment modalities available, management of cervical cancer and pregnancy should be individualized based on patients understanding and desire to maintain the pregnancy, gestational age, pregnancy outcome, tumor stage and oncological safety of pregnant women and the fetus. The work-up evaluation includes clinical examination, histological confirmation (cone biopsy should be avoided), ultrasonography of abdomen and pelvis to evaluate primary and gross nodal disease and kidney status and if required MRI abdomen and pelvis. CT or PET-CT imaging should be avoided.

In general, based on the patient’s performance status, comorbidities, stage and gestational age, appropriate management, including proper counseling on risk and benefits, prtcome, and treatment are planned.

In patients with noninvasive disease, all attempts should be made to preserve pregnancy (if desired) and conservative LEEP, conization with cerclage, diathermy or delay in definitive treatment options should be discussed [49–51].

In patients with invasive disease, radical surgery, including removal of the tumor (conization, simple or radical trachelectomy) and LN staging according to the stage of the disease with the intent to preserve the pregnancy or radical surgery/primary chemoradiation as recommended for the stage of the disease without preservation of the pregnancy, with or without previous pregnancy termination, can be offered.

Attempts should be made to delay the oncological treatment until fetal viability (at least 24 weeks) and/or >32 weeks followed by cesarean delivery and cancer stage-specific treatment. Spontaneous delivery should be avoided. Neoadjuvant chemotherapy until fetal viability has been a successful treatment without major risks. Neoadjuvant chemotherapy can be initiated as early as 14 weeks gestation period. If the patient does not wish to preserve pregnancy, medical termination followed by stage-based appropriate treatment similar to that for the nonpregnant patient should be offered.

10 Cervical Cancer and HIV

In patients with retroviral positive, there is higher incidence of in situ and invasive cervical cancer and usually diagnosed at an earlier age as compared to negative patients [52]. Antiretroviral therapy (ARV) should be integrated in the treatment because it reduces AIDS-related causes of death by 75%. The medical management of retroviral positive and AIDS patients diagnosed with cervical cancer should follow the general guidelines for the treatment of cervical cancer.

Treatment offered depends on the stage of disease and general performance status, irrespective of their retroviral status. The radiation therapy details remain similar to other patients. These patients are at higher risk of toxicities (acute and late) due to low immune status and hence need more rigorous monitoring [52].The indication for chemotherapy is tailored to the performance status and immune status of the patient. Chemotherapy is avoided if the CD4 count is below 200 cells/mm^3. Patients receiving chemotherapy are at higher risk for myelosuppression; hence, careful monitoring is required.

11 Management of Other Histologies

11.1 Adenocarcinomas, Adenosquamous, Adenoid Cystic Carcinomas

These histologies, although not common, are biologically aggressive and associated with poor prognosis as compared to classical squamous carcinoma histology. Hence, aggressive treatment protocols are attempted to achieve optimum outcome for, for example, neoadjuvant chemotherapy, radical surgeries, concomitant chemoradiation and adjuvant chemotherapy.

11.2 Neuroendocrine Small Cell Carcinomas

Patients with small cell carcinomas of cervical cancer are approached based on the experience from the lung variant small cell carcinoma, utilizing cisplatin etoposide-based chemotherapy and concomitant chemoradiotherapy with or without prophylactic cranial radiation. The outcome is unfavorable, with 3-year survival less than 30%.

12 Management of Recurrent Disease

Based on various factors like sites, single or multiple, performance status, comorbidities, etc. an upfront decision on curative versus palliative treatment is vital. Treatment of recurrent disease with curative intent requires super-centralization, involvement of a multidisciplinary team including gynecologic oncologist, radiation oncologist, radiologist, pathologist, medical oncologist, urologist, plastic surgeons, etc. and tumor board discussions.

Diagnostic work-up to identify exact patterns of relapse, locoregional, distant and combination of relapses and histological confirmation of recurrence should be performed.

Patients with multiple nodal, distant metastasis or multiple locoregional or fixed pelvic wall are usually considered for palliative treatment only, while others are candidates for curative salvage treatments after proper counseling about the risks, side effects, consequences and QOL.

12.1 Local Recurrence After Primary Surgery

Central or lateral pelvic recurrences after surgery are treated by chemoradiation and BT or pelvic exenteration in selected patients only. Chemoradiation or radiation therapy alone with interstitial BT results in optimal outcome with reasonable acceptable toxicities [53]. Pelvic exenteration may be an alternative (particularly if a fistula is present) in selected patients without pelvic sidewall involvement. Alternately, whole pelvic radiochemotherapy followed by a stereotactic ablative boost or stereotactic ablative radiation with newer radiation techniques including photon or particle beam are emerging and should be encouraged to participate in clinical research.

12.2 Local Recurrence After Primary Radiotherapy

Selected patients with isolated central recurrences should be considered for pelvic exenteration. The relative indications include patients with resectable central recurrences that involve the bladder and/or rectum and resectable pelvic sidewalls without evidence of intraperitoneal or extrapelvic spread. However, majority of patients are not suitable for surgery due to poor performance status, low albumin and high morbidity rates.

Role of chemotherapy before surgery in the management of recurrent disease is currently unclear. Not more than two to four courses of combination chemotherapy should be given to avoid unnecessary long interval before definitive surgery or radiotherapy. Locoregional recurrences, which at diagnosis appear incurable should be reassessed for the possibility of radical treatment if major response to chemotherapy (2–4 cycles) is obtained. The role of biological target agents is currently unclear. There is currently limited evidence to support the use of adjuvant chemotherapy following radical surgical treatment of the recurrence. However, adjuvant chemotherapy can be considered in cases carrying a high risk of recurrence such as positive margins, positive LN, or LVSI-positive tumors. Suitable candidates for adjuvant chemotherapy are patients who recover well within 2 months after primary treatment for recurrence.

Other spectrum of recurrence include, triad of unilateral leg edema, sciatic pain and ureteral obstruction almost always indicates unresectable disease on the pelvic sidewall, and are usually offered palliative treatments only.

13 Prognosis and Outcome

The most important prognostic factor for cervical cancer is staging including nodal disease. In patients with node-negative disease, outcome depends on local staging. Hence, clinical examination and imaging for local staging become vital. Similarly, in node-positive patients apart from local staging, imaging/surgical sampling to identify pathological regional nodal disease defines the outcome in cervical cancer.

In patients with early cervical cancer who undergo radical surgery, the surgicopathological factors related to resection status, histology type, grade, depth of stromal invasion, LVSI, tumor dimension, cut margins, positive parametrial and nodal disease are important tumor-related prognostic factors that also form the basis for risk-adapted treatment approach. Apart from these, nodal yield, number of nodes positivity, etc. also are important for disease outcome.

For locally advanced disease, apart from local and nodal staging, other tumor and treatment-related factors including, type of tumor (exophytic versus endophytic), presence of necrosis, uterine corpus invasion, hydronephrosis, unilateral or bilateral parametrial involvement, imaging biomarkers like PET uptake values, restricted diffusion on MR, response to chemoradiotherapy, residual disease at brachytherapy, radiation doses, compliance to completion of treatment (overall treatment time <8 weeks), adequate chemotherapy cycles and doses define the outcome of the patients.

Patient-related prognostic factors include age, smoking, anemia, high pretreatment leukocyte counts, presence of pelvic inflammatory disease (PID), previous pelvic surgeries, retroviral infection status and nutritional status also influence the treatment, compliance and disease outcome.

13.1 Disease Outcome

In early stage invasive cancers (FIGO I-IIA), the 5-year survival rates reported with various treatment modalities range between 88% and 95%. As described earlier, all attempts should be made to offer single-modality treatment to minimize the treatment-related late effects and improve the QOL. For locally advanced disease treated with radical intent, with radiation therapy alone, 5-year survival rates of 65%–75%, 35%–50% and 30% have been shown for FIGO IIB, IIIB and IVA, while contemporary series of chemoradiation have shown further improvement in 5-year survival by 7–10%.

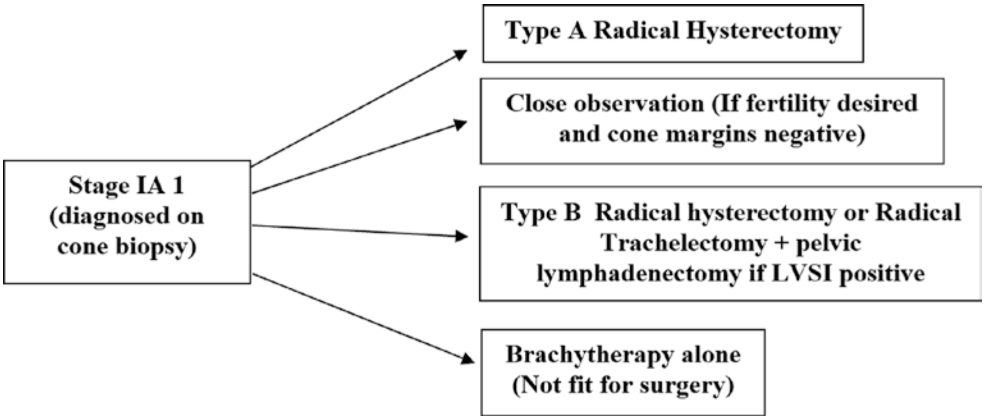
13.2 Follow-Up

After completion of treatment and establishing complete response, all patients should be counseled for regular follow-up for early detection of recurrence, treatment-related complications, and rehabilitation, including change in lifestyles.

More than 80% of recurrences are seen within 2 years after the treatment; hence, follow-up should be more intense during this period—once every 3–4 months for the first 2 years followed by every 6 months for the next 3 years and annually subsequently. All patients should be evaluated by experienced team to identify early recurrences and treatment-related side effects. Follow-up evaluation should include patient history with elicitation of relevant symptoms and physical examination including a speculum examination and bimanual pelvic examination. Imaging and laboratory tests are not routinely advocated in asymptomatic patients [54]. Suspicious lesions should be biopsied. The vaginal vault cytology has low positive predictive value to detect recurrence in asymptomatic population especially postradiation and is therefore not routinely recommended. Patients should be encouraged and educated regarding regular use of vaginal dilators and sexual activity (if applicable) to avoid long-term vaginal toxicities.

Hormone replacement therapy should be offered, especially to the younger patients who are long-term survivors, as per the premature menopausal management guidelines. Combined estrogen–progesterone preparations are generally given to patients with uterus in situ, while estrogens are given to patients who have undergone hysterectomy.

Treatment Algorithms According to FIGO (2018) Staging—Cervical Cancer (Figs. 6, 7, 8, 9, 10, 11, 12, 13)



Stage IA 1
(diagnosed on
cone biopsy)
Type A Radical Hysterectomy
Close observation (If fertility desired
and cone margins negative)
Type B Radical hysterectomy or Radical
Trachelectomy + pelvic
lymphadenectomy if LVSI positive
Brachytherapy alone
(Not fit for surgery)

1 Introduction

The incidence of preinvasive vulval cancers has increased over the past 30 years, owing to increased awareness and detection of vulvar intraepithelial neoplasia and also their more effective treatment thus preventing the development of vulvar cancer. The incidence of vulvar squamous cell cancer (VSCC), on the other hand, has remained relatively unaltered. An analysis of 13,176 patients in the SEER (Surveillance Epidemiology and End Results) database between 1973 and 2000 found that VIN increased by 411%, while VSCC only increased by 20% [1]. Cancer registry in India, as in 2015, showed a heterogeneous incidence of vulvar carcinoma across the country. During the year 2003–2007, the crude rate was 0.2–0.5 per 100,000 women per year. A pooled incidence in different cities showed a rise in incidence between the age groups of 50 and 70 years [2]. Most vulval cancers occur in postmenopausal women in the seventh decade, although recent reports have identified a trend toward younger age at diagnosis.

2 Aetiology

There are two distinct aetiopathogenic pathways leading to vulval cancer, associated with either: (A) VIN of usual type (uVIN) which is human papillomavirus (HPV)-driven or (B) VIN of differentiated type (dVIN) which develops independently of HPV.

High-grade squamous intraepthelial lesion (HSIL) is the precursor lesion of warty and basaloid vulvar squamous cell carcinoma. dVIN is the precursor lesion of keratinising SCC, which is the most frequent subtype of vulvar cancer, accounting for 63–86% of all cases. Typically, SCC occurs in older menopausal women and is not associated with HPV. Among HPV serotypes, 16 is the most common; however, many other serotypes, including 18, 31, 33 and others, have been implicated. HPV DNA can be identified in approximately

85% of intraepithelial lesions (range, 42%–100%), but is seen in only 10%–50% of invasive lesions [3].

Basaloid or warty carcinomas are associated with the well-known risk factors for cervical carcinoma, including age at first intercourse, lifetime number of sexual partners, prior abnormal Pap smears, smoking, lower socio-economic status and chronic immune-suppression. Keratinising SCC vulva is linked to chronic vulvar inflammatory lesions, such as vulvar dystrophies, including lichen sclerosus, lichen planus, lichensimplex chronicus, squamous cell hyperplasia and differentiated VIN (dVIN) [4].

3 Pre-Invasive Disease of the Vulva

Squamous premalignant lesions of the vulva were first recognised a century ago, and since the initial description, numerous terms and classification schemes have been proposed. Bowen's disease was first described by the dermatologist J.T. Bowen in 1912. The 1976 International Society for the Study of Vulvovaginal Disease (ISSVD) endorsed the term 'squamous cell carcinoma in situ' and 'hyperplastic dystrophy'. The latter was further qualified by mild, moderate or severe atypia. The term 'intraepithelial neoplasia' was first proposed by Richart in 1967 and subsequently by Crum in 1982. In 1986, the ISSVD adopted the term VIN which was graded as VIN I, II and III.

There is evidence accumulating that VIN 1, 2 and 3 does not exist on a biological continuum, as the classification implies. VIN 1 consists almost entirely of condyloma acuminatum and is associated with low-risk HPV types 6 and 11. VIN 2 and 3, on the other hand, are true premalignant lesions with risk of progression to vulvar cancer and are associated with high-risk HPV types. Based on these aetiological and prognostic differences, the ISSVD in 2004 removed VIN 1 due to its negligible risk for cancer progression. It proposed a 2-tier classification scheme: (A) uVIN (including lesions previously classified as VIN 2 and VIN 3) and (B) dVIN. uVIN was subdivided into warty, basaloid and mixed types [5].

In 2012, College of American Pathologists (CAP) and American Society for Colposcopy and Cervical Pathology (ASCCP) recommended the Lower Anogenital Squamous Terminology (LAST) nomenclature, unifying the terminology applied to all HPV lesions involving the cervix, vulva, vagina, anus, perineum and penis, under two headings: (A) low-grade squamous intraepithelial lesion (LSIL) and (B) high-grade squamous intraepithelial lesion (HSIL). LSIL is equivalent to uVIN 1 and HSIL encompasses uVIN 2 and uVIN 3. The two-tier system is likely to be more reproducible and prognostic than earlier systems.

3.1 Clinical Features and Presentation

3.1.1 VIN, Usual Type

uVIN most commonly occurs in young women, in the third to fifth decades of life. Risk factors include smoking, number of sexual partners and immunosuppression. HPV infection is strongly associated with uVIN. Most patients complain of pruritus or dysuria. uVIN presents as white or erythematous macules or papules, which can coalesce to create verrucous plaques. Less commonly, the lesions can be pigmented. Over half of patients have multifocal lesions in the vulva, and 18–52% have squamous dysplasia at other ano-genital sites, particularly the cervix. Thus, all the patients with the diagnosis of VIN should undergo a thorough examination of the anogenital region with or without colposcopy and also performance of cervico-vaginal Pap smears.

The rate of progression of uVIN to invasive cancer has been reported to be less than 5%. The most important risk factors for malignant progression included advanced age and immune-compromised status. VIN recurs in approximately 13–36% of patients. In majority of the cases, it remains unclear whether the lesions represent true recurrences or acquisition of new lesions, given the 'field effect' of HPV infection.

3.1.2 VIN, Differentiated Type

dVIN typically occurs in older women in the sixth to eighth decades of life. dVIN is often associated with adjacent lichen sclerosus (LS) and/or chronic inflammatory dermatoses. In comparison to uVIN, dVIN tends to present as a unifocal lesion which may appear as focal grey-white discolouration with a rough surface, or vaguely defined thick white plaque, or an elevated nodule.

dVIN may be more likely to progress to VSCC than uVIN as dVIN may be found adjacent to VSCC in almost 40% of the cases [6].

3.2 Diagnosis

Colposcopic evaluation of the complete lower genital tract with directed biopsy should be a standard protocol in the diagnostic assessment of preinvasive vulvar disease. Colposcopy may permit identification of previously unidentified, subclinical lesions and better define the distribution of clinically evident disease and also to rule out cervical preinvasive disease. This is particularly the case if ablative treatment is being considered, either alone or in combination with excisional procedures. Biopsies are best taken with a Keyes biopsy instrument under local anesthesia in the office setting.

3.3 Treatment

Treatment is aimed at control of symptoms and prevention of progression to invasive cancer.

Surgery (excision or ablation) is the standard treatment, but this approach can be disfiguring causing physical and psychological problems and does not guarantee cure as recurrence rate is 30–60% [7]. Recently, evidence on activity, safety and feasibility of medical treatment of VIN has emerged. If occult cancer is suspected despite a biopsy diagnosis of VIN, surgical excision remains the treatment of choice.

3.3.1 Medical Treatment of VIN

Two candidate drugs identified for topical use for VIN are cidofovir and imiquimod. Cidofovir is a nucleoside analog with antiviral properties, and imiquimod is an immune response modifier. Tristram in 2012 reported a multicentre, randomised, phase 2 trial to assess the efficacy of these two topical treatments as an alternative to surgery in 180 women with biopsy proven VIN grade 3. Patients were randomly allocated to topical treatment with either 1% cidofovir gel or 5% imiquimod (one 250 mg sachet for every application), to be self-applied three times a week for a maximum of 24 weeks. 46% of women in each group had complete response at the post-treatment assessment visit 6 weeks after the end of treatment. They concluded that cidofovir and imiquimod were active, safe and feasible for treatment of VIN and were effective alternatives to surgery [8].

Long-term follow-up data of complete responders from the above trial indicated a trend towards response being maintained for longer following treatment with cidofovir than with imiquimod, with similar low rates of adverse events for each drug [9].

A Cochrane review on medical versus surgical interventions for treating uVIN concluded that topical treatment (imiquimod or cidofovir) may effectively treat about half of uVIN cases after a 16-week course of treatment. Factors predicting response to treatment are not clear, but small lesions may be more likely to respond. The relative risk of progression to vulvar cancer is uncertain. Women who undergo surgical treatment for uVIN have about a 50% chance of the condition recurring 1 year later, irrespective of whether treatment is by surgical excision or laser vaporisation. Multifocal uVIN lesions are more difficult to treat and are at a higher risk of recurrence and progression. Combined modalities may hold the key to optimal treatment of VIN [10].

3.4 Surgical Interventions

3.4.1 Wide Local Excision and Superficial Vulvectomy

Localised high-grade VIN lesions are managed by local, superficial excision with a disease-free margin of at least 5 mm. Wide local excision is mandatory if a lesion has warning signs of possible invasive cancer. Surgical excision with disease-free margins achieves a 90% cure rate for localised disease. If the margins are involved with disease, the cure rate falls to 50%, demanding very close follow-up [11].

Large, confluent lesions or extensive multifocal disease, particularly in the presence of colposcopic warning signs of early invasion, require more extensive excisional procedures with rotational flaps to fill the defect, or superficial (skinning) vulvectomy with a split-thickness skin graft.

3.4.2 CO_2 Laser Surgery

CO_2 laser ablation under colposcopic control may be the preferred treatment in young patients with large lesions in whom restoration of anatomy is desirable [12].

The initial 2 weeks following more extensive laser ablative procedures may be associated with significant pain, particularly with micturition. The use of appropriate laser technology and settings, advanced surgical expertise with careful control of depth of ablation, and appropriate postoperative care will mitigate much of the potential morbidity. CO_2 laser ablation is particularly useful in patients with periclitoral and peri-anal disease, where the preservation of anatomy and function is important.

3.5 HPV Vaccination

The FUTURE I and FUTURE II trials of the quadrivalent vaccine against HPVs 6, 11, 16, and 18 have demonstrated very high levels of protection against future development of usual-type VIN [13]. The use of vaccination against HPV 16 oncoproteins as a therapeutic strategy for women with usual-type VIN also appears very promising [14]. The combination of imiquimod treatment with HPV vaccination may offer another non-surgical approach to the treatment of VIN. A recent British Phase II trial evaluated the treatment of VIN using imiquimod followed by an HPV therapeutic vaccine (TA-CIN, Fusion Protein HPV 16 E6E7L2) [15]. Complete histologic regression was observed in 32% of women at week 10, increasing to 58% at week 20 and 63% at week 52. These results are promising and results of larger trials and long-term follow-up are awaited.

3.6 Follow-up

Treatment of VIN should be individualised according to age, distribution of the lesion, severity, associated disease and previous treatment. Close follow-up after treatment remains essential because of the risk of recurrent disease. Most recurrences occur within 3 years of treatment. Positive excision margins, multifocal disease, smoking and immune-suppression are associated with increased recurrence rates.

4 Vulval Cancer

4.1 Introduction

Malignant tumours of the vulva are rare and account for less than 5% of all cancers of the female genital tract. Squamous cell carcinomas account for 85–90% of cases, whereas melanomas, basal cell carcinomas, invasive Paget's disease, Bartholin gland carcinomas, neuroendocrine, merkel cell tumours and sarcomas are less common. Most vulval malignancies arise within squamous epithelium. Squamous neoplasms arise most commonly on the labia minora, clitoris, posterior fourchette, perineal body or medial aspects of the labia majora. Malignant melanoma of the vulva accounts for <10% of all primary malignant neoplasms on the vulva, and vulval melanoma accounts for approximately 3% of all melanomas in women. Vulval Paget's disease occurs in older women. Approximately 15% of women with vulvar Paget's disease have underlying primary adenocarcinoma, usually arising within apocrine glands or the underlying Bartholin's glands.

4.2 Clinical Presentation

Most women with vulvar cancer present with pruritus and a recognisable lesion. Less common presenting symptoms include vulvar bleeding, discharge, dysuria, or occasionally a large metastatic mass in the groin. On physical examination, the lesion is usually raised and may be fleshy, ulcerated, leukoplakic or warty in appearance. Warty lesions are often initially misdiagnosed as condylomata acuminata. Vulval Paget's disease typically presents as an eczematoid, red, weeping area on the vulva, localised to the labia majora, perineal body, clitoral area or other sites. This disease usually occurs in older women, although rarely can occur in a premenopausal woman. Vulval melanoma may arise from a pre-existing pigmented lesion or from normal-appearing skin. The primary site on the vulva may be the clitoris, labia minora and labia majora with predominant symptom as bleeding.

4.3 Pre-treatment Evaluation

Patient presenting with a suspicious lesion should undergo a diagnostic biopsy. Selecting the most appropriate site for biopsy in women with condyloma, chronic vulvar LS, multifocal VIN 3 or Paget's disease can be difficult, and colposcopic guidance with multiple biopsies may be required. Tissue biopsies should include the cutaneous lesion in question and representative contiguous underlying stroma, so that the presence and depth of invasion (DOI) can be accurately assessed. If invasion is suspected and a punch biopsy fails to confirm the clinical suspicion, then an incisional biopsy should be performed. Diagnostic excisional biopsy is to be strictly avoided, to facilitate the sentinel node procedure and fashion adequate surgical margins at the time of definitive surgery.

A detailed clinical examination with measurements of the primary tumour, assessment for extension to adjacent important mucosal or bony structures and assessment of the inguino-femoral lymph nodes should be performed. It is important to obtain pretreatment pictures and record not only the anatomical extent of lesion but also the distance from vital structures such as the clitoris, urethral meatus and anus, since these structures may be a limiting factor for obtaining adequate surgical margins. A detailed mapping is also of great assistance to plan brachytherapy after external radiation in patients where treatment is contemplated with primary radiation therapy and not surgery. Whenever needed examination under anesthesia should be done to map the pre-treatment disease extent. Careful examination of vagina, cervix and anal canal should also be undertaken to rule out multi-focality.

Suspicious lymph nodes on physical examination or imaging should be subjected to fine-needle aspiration cytology or biopsy if the findings would alter the therapeutic plan. For patients with very extensive lesions, cysto-urethroscopy and/or procto-sigmoidoscopy may be done. CT scan should be obtained in patients to known extent of inguino-pelvic and abdominal lymph node involvement. Chest X-ray should be obtained to rule out lung metastasis. PET may be useful in evaluating patients with vulvar melanoma for distant metastases. A role for PET in squamous cancer has not been established.

Staging for vulvar cancer can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 636–637, Chapter no. 50, Vulva Table: Definition of TNM and AJCC prognostic stage groups which can be accessed at https://emedicine.medscape.com/article/2156984-overview

4.4 Management

4.4.1 Principles of Management

Management of vulval cancer requires a multidisciplinary team approach. Successful centralisation of the management of patients with vulvar cancer especially in tertiary cancer centres has been shown to be associated with improved survival. Standard treatment for early-stage disease is radical wide local excision of the primary tumour with or without inguinal–femoral lymphadenectomy or sentinel lymph node mapping/biopsy. The decision to address lymph nodes is based on DOI and thickness. Stage I squamous carcinomas of the vulva with a DOI ≤1 mm are associated with <1% risk for lymph node metastasis. Tumours with a DOI of 1.1–3.0 mm are associated with lymph node metastases in 6%–12% of patients and approximately 15%–20% with a DOI of 3.1–5.0 mm [16]. Hence, all stage 1 vulval squamous cell carcinoma with DOI >1 mm should undergo inguinal–femoral lymphadenectomy or sentinel lymph node mapping/biopsy along with radical excision of the primary vulval tumour.

Lymphovascular space involvement is also associated with a higher frequency of lymph node metastasis. The International Society of Gynecologic Pathologists (ISGYP) recommended that the pathology report should include information on diameter of tumour (specifying measurement conditions), depth and thickness of tumour invasion and presence of absence of lympho-vascular space invasion. Survival is improved with postoperative radiation therapy to selected patients deemed to be at high risk for loco-regional failure. For locally advanced vulval cancers, neo-adjuvant radiotherapy with concomitant radio-sensitising chemotherapy has proven to be effective in treating vulval cancer patients for whom radical surgery would be either too morbid or to prevent urinary or fecal diversion stoma. If surgery is not envisaged after neo-adjuvant chemo-radiation, then boost radiation should be used (either brachytherapy or external) to maximise local control.

4.4.2 Stage-Wise Management

Stage I/II Tumours

Tumours ≤2 cm in Size with DOI of the Vulvar Stroma ≤1 mm

Superficially invasive carcinomas have minimal risk for lymphatic dissemination. Radical wide local excision with a 1-cm normal tissue margin is the treatment of choice. Patients in this category represent the only subset for whom inguinal femoral lymph nodal dissection can be avoided. These early superficially invasive carcinomas tend to arise in younger patients with VIN and are more likely to be associated with high-risk HPV infections.

Tumours with DOI of the Vulvar Stroma of >1 mm, >2 cm in Size

Radical wide local excision of the primary tumour or radical vulvectomy with unilateral or bilateral sentinel lymph node biopsy (SLNB) +/− inguinofemoral lymphadenectomy is now the standard treatment. The procedure removes the primary tumour with a wide radial margin of normal skin (1–2 cm), along with a deep margin to the deep perineal fascia [17]. Radical vulvectomy may sometimes be indicated for very large tumours. Vital structures like urethral meatus and clitoris should be preserved whenever possible to avoid psychosexual consequence especially in young females.

With careful planning of surgical excision and adequate tissue mobilisation, most vulvar defects can be closed primarily. With larger vulvar resections or poor tissue mobility, primary closure may not be feasible and planned vulvar reconstruction with fascio-cutaneous advancement flaps and myocutaneous flaps must be considered. A study from Kentucky analysed 122 vulval cancer patients with T1 and T2 lesions from 1963 to 2003. Radical vulvectomy was performed on 49% patients and radical hemi-vulvectomy on 51%. Inguino-femoral node metastases were present in 11% of patients with a T1 lesion and 31% of patients with a T2 lesion. Disease-free survival of patients was excellent in both the groups being 98% and 93% for T1 and T2 lesions, respectively, at 5 years. Local or distant recurrence was not more common in patients with radical local resections versus those treated by radical vulvectomy [18].

Sentinel Inguinal Lymph Node Biopsy (SLNB)

The SLNB is defined as the first draining lymph node of a tumour which can be identified by lymphatic mapping. Preliminary experience with both intraoperative lymphatic dye and radioisotope injections confirmed that the SLN of the vulva is always in the groin and can be identified in most patients [19].

This early experience formed the basis of 2 large multi-institutional trials that aimed to determine the feasibility and safety of SLNB in women with early-stage vulval cancer. The GROINS V trial that enrolled 403 evaluable women with tumours ≤4 cm who underwent SLNB alone with 623 groin dissections. Metastatic sentinel nodes were found in 163 groins (26.2%) 0.276 women had a negative SLNB and were closely observed for recurrence during a 2-year follow-up period. 2.9% of these 276 women suffered a groin relapse. When patients with multifocal primary tumours were excluded from the analysis, the relapse rate was only 2.3%. Morbidity was significantly decreased in patients undergoing sentinel node biopsy only [20].

In Gynecological Oncology Group (GOG) 173, 418 evaluable women underwent SLNB followed by unilateral or bilateral inguino-femoral lymphadenectomy depending on whether the tumour was a lateral or a midline tumour. The false-negative rate was 8.3%, and the false-negative predictive value (FNPV), i.e., was 3.7% for the entire cohort. The FNPV is a prediction of the chance of a positive non-sentinel lymph node when the SLN is free of tumour and a lymphadenectomy has not been performed. In GOG 173, the FNPV by groin was 2.7%; for patients with tumours less than 4 cm, it was 2.0%. This means that a patient with a tumour less than 4 cm, no palpable lymph nodes and a negative SLNB has a 2% chance of a positive groin node [21].

The results of these studies indicate that, for women with primary tumours ≤4 cm, no palpable groin nodes, in the care of a surgeon experienced with the technique, the risk of groin relapse following a negative SLNB is 2%–3%. Before implementing this technique as standard, each gynaecologic oncologist should determine his or her own false-negative rate by performing SLNB followed by inguino-femoral lymphadenectomy in approximately 10 cases. Ideally, all vulval cancer patients should be treated at high-volume referral centres. In both GOG 173 and GROINS V, half of the lymph node metastases were detected by pathologic ultra-staging with serial sectioning (3 sections per mm) and immunohistochemistry (IHC) with cytokeratine (AE1/AE3) if routine H&E staining did not reveal metastatic disease. Thus, SLNB has the promise of reducing the unnecessary lymphadenectomy performed in node-negative women while at the same time identifying additional women who may benefit from adjuvant therapy.

If a sentinel node is positive, the patient requires adjuvant treatment for the groin. A review of the Groningen study reported that there was no cut-off in the size of the metastatic focus in the sentinel node below which the chances of non-sentinel node metastases were close to zero [22]. If there is failure to detect sentinel node, it is important to undertake complete inguino-femoral lymphadenectomy.

Long-term follow-up of GROINNS V study with median follow-up of 105 months showed that disease-specific 10-year survival was 91% for SN-negative patients compared to 65% for SN-positive patients [23]. Also, it is important to note that the above treatment algorithm applies to patients with vulval cancer <4 cm with no metastatic groin node preoperatively. If metastasis is proven in groin nodes preoperatively, then inguino-femoral lymphadenectomy should be the treatment of choice. Unilateral lymphadenectomy may be considered in patients with well-lateralised lesions. Contralateral lymphadenectomy should be considered if ipsilateral nodes are positive.

Key surgical anatomical landmarks with standard incisions for local resection of the vulval tumour and inguino-femoral lymphadenectomy are shown in Figs. 1, 2, 3, 4. Details of the steps of surgery along with surgical illustrations are depicted in Atlas of operative surgical oncology published by Tata Memorial Hospital [24].

4.5 Adjuvant Radiation

4.5.1 Primary Site

Close surgical margin portends high risk of local recurrence following. Recurrence has also been correlated to tumour size, lymphovascular space invasion and deep tumour penetration. Adjuvant radiation to vulva should be considered in patients with large tumour (>3 cm) with depth of invasion >5 mm, pathological margin ≤8 mm or other pathological high-risk features (like deep invasion and lymphovascular space invasion). In such cases, local radiation should be considered only to vulva in patients with risk features of local relapse (Fig. 5). Prophylactic postoperative groin irradiation is not recommended for a surgically negative groin.

4.5.2 Nodal Irradiation

Survival benefit is reported in those with pathologically involved groin nodes with the use of adjuvant radiation. Data from GROINSS-V study indicate that adjuvant radiation may have survival benefit in patients with one positive inguinal node, as patients with sentinel node metastasis >2 mm had reduced disease-specific survival (69.5%) than those with sentinel node metastasis ≤2 mm (94.4%, $p = 0.001$) suggesting need for more aggressive local treatment [25].

GROINSS-VII study recently reported the role of radiotherapy (50 Gy/25#/5 weeks) in women undergoing sentinel lymph node biopsy and who had micro-metastases (deposits ≤2 mm); however, excessive relapse was observed with radiotherapy alone in those with macrometastasis suggesting the need of inguino femoral lymphadenectomy +/− radiotherapy in those with more than one lymph node metastasis and/or extracapsular extension. The role of addition of concurrent chemotherapy or escalated doses of radiation in the setting of SLN biopsy and macro-metastasis is presently under investigation in a separate GROINSS V study [26].

To define the optimal treatment for patients with involved inguinal nodes following radical vulvectomy and inguinal lymphadenectomy, GOG published results of 114 patients with inguinal metastases [25]. Those with involved inguinal nodes were randomised intra-operatively to receive either pelvic node dissection or postoperative irradiation to the pelvis and inguinal nodes. The patients in the radiation group had significantly improved 2-year survival (68%) than patients in the lymph node dissection group (54%; $p = 0.03$). Groin recurrence occurred in 5.1% patients in RT arm as compared to 23.6% in pelvic lymphadenectomy arm ($p = 0.02$).

Treatment portals in such case should include ipsilateral groin and pelvic lymph nodes (upto common iliac bifurcation). The lateral extent of the planned treatment field should encompass the region of surgical dissection. An example of the postoperative treatment portals is depicted in Fig. 6. If there has been invasion of overlying skin, inclusion of an additional 5 cm of the skin flaps is recommended. Adequate care should be taken to use bolus material to ensure optimal dose to the skin. While a dose of 45–50 Gy is recommended for patients with R0 resection, a higher dose is recommmended (50–60 Gy) in patients with extra-capsular extension. Also, selective gross nodal boost up to 65–70 Gy should be considered in those undergoing partial or suboptimal nodal resection. Wherever feasible intensity-modulated radiotherapy (IMRT) should be considered as it is use is associated with no reported acute or late Grade 3–4 gastrointestinal or genitourinary toxicity [27].

A recent review of the 1797 patients within the national cancer database suggests increasing use of adjuvant chemotherapy along with radiation, which was associated with reduction in the risk of death (HR 0.81, 95% CI 0.65–1.01 $p = 0.059$). Also, the median survival improved by almost 14 months (from 29.7 to 44 months) resulting in 3-year survival of 54% (as compared to 47%) ($p = 0.001$). Therefore, adjuvant chemo-radiation should be considered for patients with positive groin nodes [28].

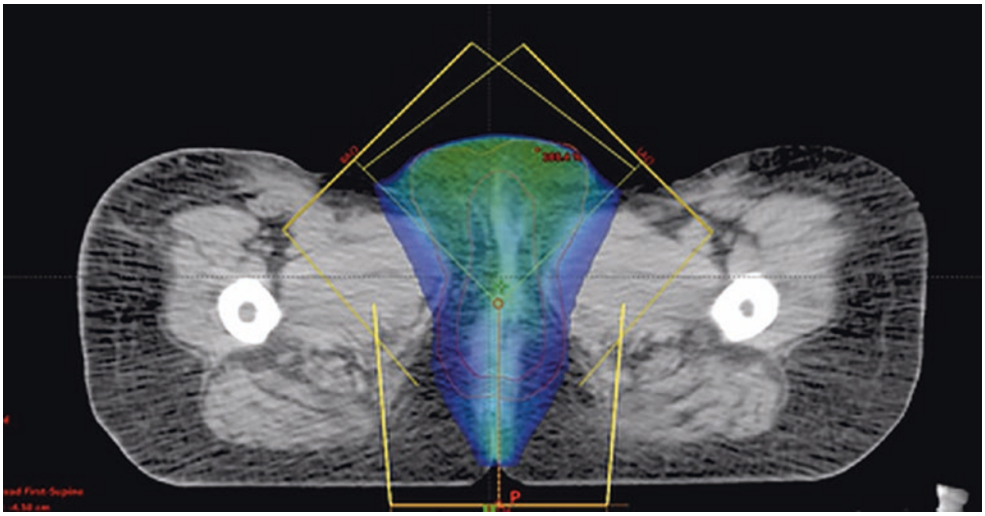

Fig. 5 Figure depicting target for vulva (postoperative) only using 3-field conformal irradiation technique

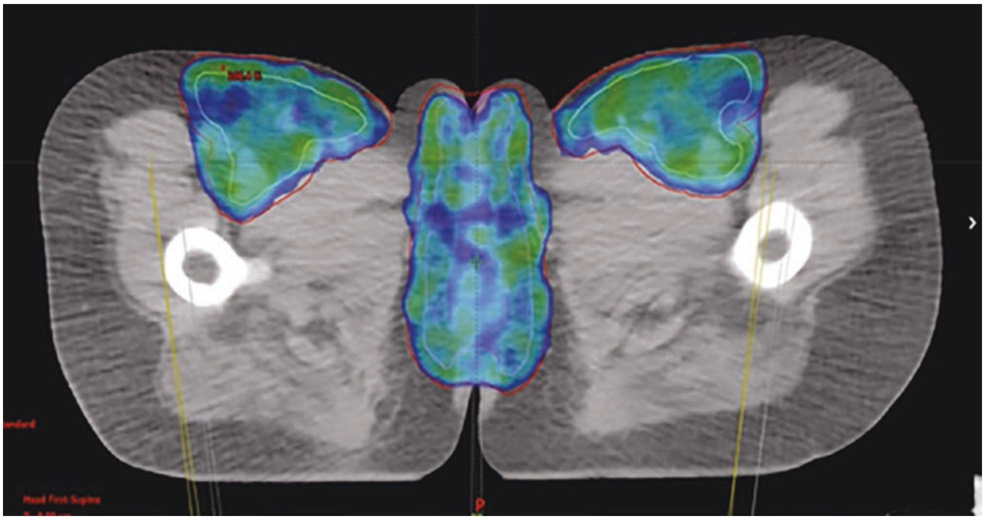

Fig. 6 Figure depicting primary and nodal irradiation for patient with locally advanced vulvar cancer using intensity-modulated radiotherapy

4.5.3 Stage III and IV

Tumours that have involved adjacent important mucosal structures (upper urethra, vagina, bladder or rectum) with or without enlarged inguinal nodes are best managed with sequenced multimodality approach. Some primary tumours may be amenable to curative resection with infralevator pelvic exenteration along with radical vulvectomy and inguinofemoral lymphadenectomy with reconstruction [29].

However, given the morbidity of upfront surgical procedure there has been increased emphasis on neoadjuvant radiation or concurrent chemoradiation followed by limited, more conservative, viscera-sparing surgery. In a Cochrane systematic review, no difference in overall survival amongst patients treated with primary or neoadjuvant chemoradiation or primary surgery [30].

GOG study that recruited locally advanced tumours used neoadjuvant chemoradiation (57.6 Gy and weekly cisplatin (40 mg/m^2)). Overall 69% patients were able to complete the planned treatment, 37 of 58 (64%) achieved a complete response and 29 of 58 (50%) had a pCR on biopsy. Following neo-adjuvant chemo-radiation for locally advanced disease, it is yet not clear whether surgery is necessary in those who achieve complete clinical response [31]. In GOG 101, approximately 70% of patients who achieved complete clinical response were found to have pathological complete response [32]. At this point, biopsies of the original tumour bed in patients who achieve complete clinical response and tailored surgical resection of the residual disease following chemo-radiation is recommended. Groin node dissection should be undertaken after neo-adjuvant chemo-radiation as inguinal nodal relapses cannot be effectively salvaged. If surgery is not feasible, then boost radiation should be used. Nodal and primary site should receive up to 60 Gy. Wherever feasible boost brachytherapy should be considered, however, should be considered in centres with considerable expertise in treating such tumours. Institutional experience published from Tata Memorial Centre reported 5-year local control and disease-free survival of 77% and 51%, respectively, with use

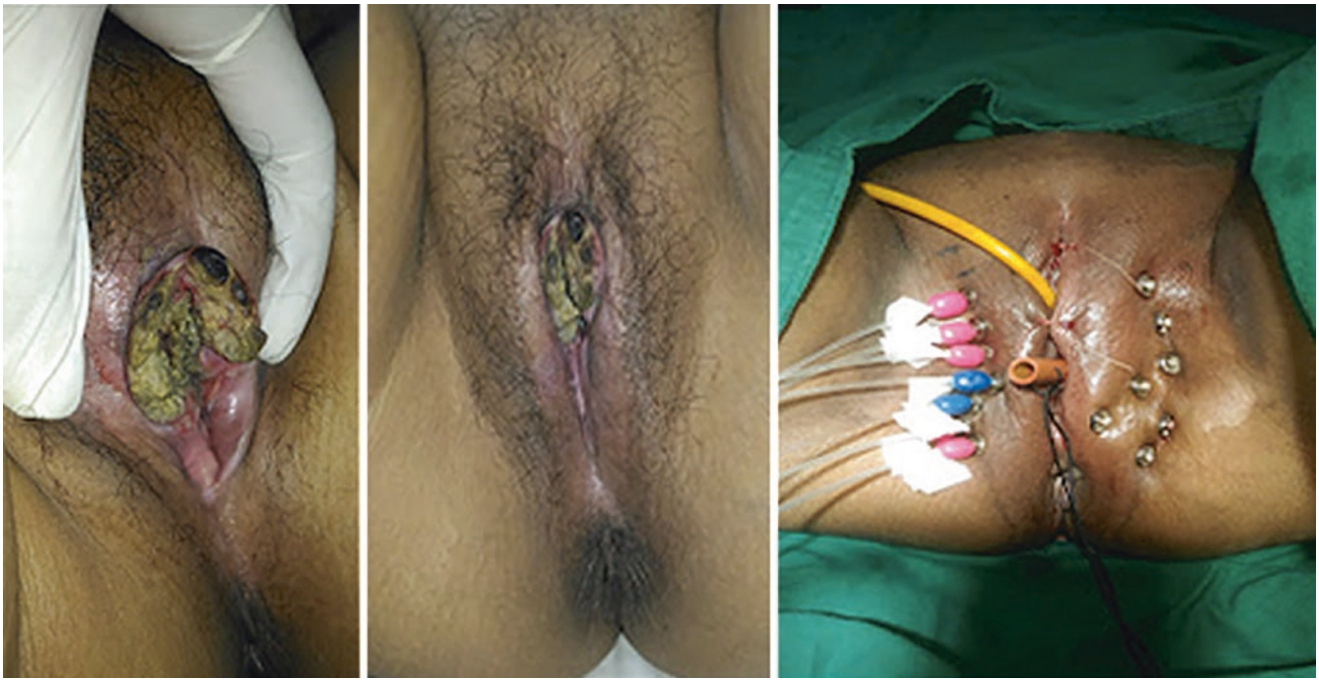

Fig. 7 Figure depicting case example of patient with vulvar cancer treated with chemoradiation and free hand interstitial brachytherapy. The composite image panel shows pretreatment lesion extent, post external radiation response and technique of free hand interstitial brachytherapy

of boost brachytherapy [33]. An example of patient undergoing chemoradiation and brachytherapy is depicted in Fig. 7.

4.5.4 Radiation Technique and Volumes

Preoperative and radical chemoradiation necessitates treatment of entire vulva, distal vagina (with adequate margins to proximal disease extent), and also nodal targets including bilateral inguinal, external, internal iliac and common iliac nodes. As the treatment target is heterogenous and complex and involves irradiating large volumes therefore advanced techniques like IMRT may provide an advantage to optimise local control and minimise toxicity. Studies using IMRT have reported no incidence of gastrointestinal or genitourinary toxicity on follow-up [34].

4.5.5 Systemic Chemotherapy

Systemic chemotherapy is recommended in patients with stage IVB disease. However, the evidence of its impact on overall survival is not clear due to small numbers. While vinorelibine, bleomycin, cisplatin and mitoxantrone have been used in various studies, at present, combination of paclitaxel and carbolatin (paclitaxel 175 mg/m^2 over 3 h and carboplatin AUC 5 over 1 h) remains the most commonly used systemic regimen for vulvar malignancies. This is on basis of its use in other primary gynaecological cancers.

One small phase II study by Horowitz et al. evaluated the efficacy and toxicity of erlotinib (150 mg daily) among patients with locally advanced, primary, recurrent or metastatic vulvar SCC. Overall clinical benefit rate was 67.5% was reported [35]. However, responses were of relatively short duration and toxicities were significant.

4.5.6 Vulvar Melanoma

Studies have shown that prognosis of patients with vulvar melanoma is worse than that of women with extragenital melanoma and squamous cell carcinoma of the vulva. Unique molecular characters of vulvar melanoma make this disease a unique subtype of melanoma.

Surgical excision is the key treatment for localised melanomas. Adjuvant radiation or chemo-radiation is used in patients with involved margins or those who cannot undergo surgery. In the pre-immune checkpoint therapy era, studies with adjuvant interferon-alfa demonstrated survival benefits in patients with regional nodal disease. But these benefits were at the cost of health-related quality of life. The targeted therapies for metastatic vulvar melanoma include those targeting B-RAF (vemurafenib, dabrafenib), MEK inhibitors (trametinib, selumetinib) and c-KIT inhibitors (sunitinib, sorafenib). The immune therapies include those targeting CTLA-4 (ipilimumab), anti PD-1 (nivolumab, pembrolizumab) and PD L1 blocking agents (atezolizumab). Combination regimens of B-RAF and MEK-targeting drugs have also been used [36, 37]. A retrospective study looking at the role of immune checkpoint inhibitors, nivolumab or pembrolizumab, in mucosal melanoma showed overall response rate of 23% in mucosal melanomas; 40% of the patients in this study had vulvo-vaginal melanoma. Hamid et al. in an exploratory, post hoc pooled analysis of

KEYNOTE-001, KEYNOTE-002 and KEYNOTE-006, evaluated the efficacy of Pembrolizumab in mucosal melanomas [38]. The study reported a response rate of 19% in comparison to the 33% observed in non-mucosal melanomas; however, notably, 75% of the responders were still having response at the time of data cut-off. The median duration of response was 27.6 months. The results of a similar study evaluating the efficacy of Nivolumab with or without Ipilimumab in mucosal melanomas were in sync with the aforementioned study [39]. These results are better compared to outcomes with conventional chemotherapy and at present these are options have widened the armamentarium of melanoma care.

4.5.7 Recurrent Vulvar Cancer

Recurrences of vulvar cancer occur in 12–37% of patients after initial treatment, depending on tumour stage at initial diagnosis and 40–80% of all recurrences occur within 2 years of initial treatment [40]. Outcome for patients who have recurrences within 2 years after initial surgery is worse compared to patients who had recurrences >2 years after initial treatment. Surgery if feasible is the mainstay of treatment of local recurrence. Surgery with adequate margins may be more difficult with increasing tumour size, especially when the tumour is close to the anus or urethra. Also, prior surgery with altered anatomy and, in particular, earlier radiotherapy can adversely affect skin healing with increased risk of wound dehiscence or infection. Reconstruction with fasciocutaneous skin flaps or V-Y skin flaps from the upper posterior thighs may be required in many cases. Inguino-femoral lymphadenectomy is the standard treatment for the groin when recurrent disease is infiltrating >1 mm stromal depth and when groin dissection was not part of the primary treatment. The safety of the procedure should be further investigated before it is implemented in the treatment of local recurrent vulvar cancer. Pelvic exenteration may be a curative treatment option for extensive locally recurrent vulvar cancer that is otherwise untreatable [29].

Patients who are not candidates for surgical salvage and have not received previous pelvic RT may be considered for full-dose salvage chemo-radiation +/− brachytherapy. Patients who have received previous pelvic radiation may be evaluated for brachytherapy alone if feasible. In select cases, reassessment for salvage local procedure can be made after giving 3–4 cycles of salvage chemotherapy; however, in vast majority of cases, treatment needs to be individualised.

Prognosis is poor in patients presenting with groin node recurrence and combination of surgery, radiation +/− chemotherapy be used. Chemotherapy alone for groin recurrence should be considered only in palliative setting when surgery or radiation is not possible.

4.6 Summary

Early squamous cell carcinoma of vulva is generally treated with surgical excision of the local disease and prophylactic inguino-femoral lymphadenectomy. Adjuvant radiation or chemo-radiation should be used in patients with adverse risk features to maximise local control. Patients presenting with locally advanced vulvar cancers should be offered neo-adjuvant chemo-radiotherapy with surgery or primary chemo-radiation and brachytherapy to avoid morbid surgery and diversion stoma. Role of systemic chemotherapy and targeted therapy including immunotherapy is evolving and currently under investigation.

5 Vaginal Cancer

5.1 Introduction

Primary vaginal cancer is a relatively rare malignancy. It constitutes 1%–2% of all gynecologic malignancies. Tumours that involve both the vagina and cervix or the vagina and vulva are classified as cervical and vulvar lesions, respectively. As with other squamous cell cancers of the gynaecologic tract, human papillomavirus (HPV) is implicated as a cauastive factor for squamous cell carcinomas of the vagina. History of in utero exposure to synthetic oestrogen diethylstilbestrol (DES) has been linked to the development of clear cell adenocarcinoma of the vagina [41].

5.2 Pathology

The relationship between vaginal intraepithelial neoplasia (VAIN) and invasive vaginal cancer is similar to the relationship of cervical in situ carcinoma and invasive cervical cancer. Histopathologically, most of the lesions are epidermoid and demonstrate full-thickness atypical mitoses or hyperchromatism. Majority of lesions are multifocal and can involve all the vaginal surfaces. Most common site of involvement is in the superior one-third of the vaginal canal.

Invasive squamous cell carcinoma is found in 75%–95% of primary vaginal carcinomas. The majority of these lesions tend to be non-keratinising and moderately differentiated. Verrucous carcinoma is an uncommon variant of vaginal squamous cell carcinoma. It is well differentiated and has low malignant potential. Other histologies include vaginal adenocarcinoma, melanoma, clear cell carcinoma, lymphoma and sarcoma [42].

5.3 Clinical Presentation

The majority of patients with vaginal cancer are symptomatic, and vaginal bleeding is the commonest presentation. The second most common presenting symptom is vaginal discharge, which occurs in 10%–15% of patients. Other signs and symptoms that occur less frequently are pain, urinary symptoms, rectal complaints, presence of a perineal mass. Up to 20% of women may be asymptomatic at the time of diagnosis, often revealed by routine clinical or smear examination.

5.3.1 Patterns of Spread

The upper vagina's lymphatics drain to the obturator, hypogastric, external iliac and common iliac nodal groups. The lower vagina has trunks that drain to the inguinal, femoral and external iliac nodes. Vaginal cancers, particularly those that involve the posterior wall, can drain to the inferior gluteal, presacral or perirectal nodes. There are considerable crossover drainage so that any pelvic lymph node group can serve as a drainage site. Lymph node involvement in patients with stage I, II, III and IV disease has been reported in upto 6%, 26%, 78% and 83% of cases, respectively. Hematogenous dissemination may occur to lung, liver and bone.

5.4 Diagnostic Work-Up and Staging

A complete history and physical examination necessary for the diagnostic workup. Careful attention should be given to the pelvic examination. Examination under anesthesia is required to delineate the extent of the tumour and should be documented as a detailed clinical diagram. Adequate biopsies of the tumour should include biopsies of the cervix as well, to rule out a cervical primary. The workup prior to therapeutic decision should include a CECT or MRI of abdomen and pelvis and chest X-ray. Cystoscopy and proctosigmoidoscopy if there is suspicion of adjacent organs is suspected. FIGO staging for vaginal cancers is summarised in Table 1.

Table 1 International Federation of Gynecology and Obstetrics Staging System for Vaginal Cancers

I	Tumour is limited to the vaginal wall
II	Tumour infiltration into subvaginal tissue not extending to pelvic wall
III	Tumour extending to pelvic wall
IVA	Tumour extension to bladder and/or rectal mucosa and/or direct extension beyond true pelvis
IVB	Distant metastasis

5.5 Stage-Wise Management

5.5.1 Carcinoma In Situ

Many forms of therapies have been used in the treatment of VAIN, including surgical excision, carbon dioxide laser therapy, radiation therapy and topical 5-fluorouracil. None has proven superior to the others. Surgical excision is usually accomplished with a wide local excision or partial vaginectomy. Because this disease is frequently multifocal, areas of CIS may be overlooked. A Schiller mucosa test may be performed to define abnormal mucosa. If there are multiple areas of abnormal mucosa, other treatment options like vaginal brachytherapy must be considered. Treatment involves the use of an intravaginal cylinder with or without central tandem to deliver radiation to the entire vaginal mucosa. High-dose rate brachytherapy doses of 7 Gy × 5# or equivalent doses may be used weekly with dose prescribed to 5 mm from the surface of cylinder [43].

5.5.2 Stage I

Primary surgery has a limited role in the management of patients with vaginal cancer because of the radicality required to achieve clear surgical margins. In stage I disease involving the upper posterior vagina, radical hysterectomy, partial vaginectomy and bilateral pelvic lymphadenectomy can be done. Radiation therapy is the treatment of choice for most of the Patients of vaginal cancer. In most cases, a combination of EBRT and intracavitary or interstitial brachytherapy is used to achieve optimal control rates [44].

5.5.3 Stage II–III

Concurrent chemoradiation and brachytherapy is the treatment of choice for stage II and III disease [45]. External-beam therapy involves treatment of vagina, perivaginal tissues, paracolpos (cervix if disease reaching close to cervix), pelvic and medial inguinal lymph nodes. Lateral inguinal lymph nodes are treated in patients with involved inguinal lymph nodes. Doses of 4500–5040 cGy/25–28 fractions are given to the pelvic field followed by vaginal or interstitial implant, which is guided by disease extent at baseline and at time of brachytherapy. The brachytherapy dose to the target should be modelled based on the residual disease at the time of brachytherapy and organ at risk tolerance. The aim should be to deliver upto 70–75 Gy EQD2 to the primary disease while minimising dose to the rectum to <75 Gy. In most cases, the tolerance of bladder is not reached. While modest outcomes have been reported in many series combining external radiation and brachytherapy, more recently better disease-free survival has been

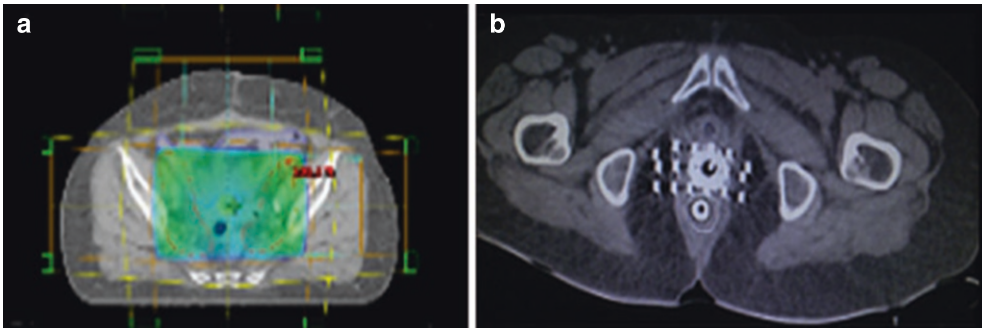

Fig. 8 (**a**, **b**) Figure depicting external beam radiation and interstitial brachytherapy technique for locally advanced vaginal cancer. Patients receive external radiation to the primary and lymph nodal drainage sites for 45–50 Gy. This is followed by intracavitary or interstitial brachytherapy is shown in panel below

reported with use of concurrent chemotherapy and integration of image-guided brachytherapy. Experience from Tata Memorial Centre using combined external radiation and chemotherapy followed by CT-based interstitial brachytherapy has been reported with 3-year disease-free survival of 64–67%. Integration of image-guided IMRT and CT-based brachytherapy is associated with 5-year DFS of 75%. Using conformal radiation and image-based brachytherapy, it is recommended that rectal doses be limited to <68 Gy to 2 cc rectal volume to minimise long-term sequelae to the rectum. Most often the optimal therapeutic ratio is achieved by combining chemoradiation with sequential fractionated interstitial template brachytherapy [46, 47]. An example of external radiation and interstitial brachytherapy is depicted in Fig. 8a, b. Recently, outcomes have been published with image-guided adaptive brachytherapy within the multicentric RetroEMBRAVE study. The study results demonstrate improved local control in T2-T4 tumours with equivalent doses >80 Gy_{10} [48].

5.5.4 Stage IVA

Individualised therapeutic management is recommended in patients with stage IV A disease. If cystoscopy reveals a small area of infiltration (<2 × 2 cm in size), then neoadjuvant chemotherapy with paclitaxel and carboplatin may be offered (2–3 cycles) followed by reassessment by cystoscopy. In patients with disappearance of fistulous communication or minimal area of fistulous communication, radical chemoradiation may be considered. Select patients may also be considered for further intra-vaginal or interstitial brachytherapy; however, treatment needs to be individualised and repeat cystoscopy may be considered prior to brachytherapy to maintain a favourable therapeutic ratio. However, if patients show no response, then palliative radiation should be considered.

Patients with a larger fistulous communication with bladder at presentation should be considered for upfront palliative radiation. Patients with fistula with rectum or sigmoid should be considered for palliative stoma followed by palliative radiotherapy.

5.5.5 Stage IV B

Palliative radiation or systemic chemotherapy should be used in patients with symptomatic stage IV B disease with principles similar to that of cervical and vulval cancers.

5.5.6 Vaginal Melanoma

The limited data available preclude definitive treatment recommendations. The overall prognosis for patients with vaginal melanoma is extremely poor, with reported 5-year survival rates of 5%–29% [48]. Distant metastases, with rates ranging from 66% to 100%, contribute to the poor outcome. While the principles of local treatment remain the same, radiation treatment should focus on use of hypofractionated radiotherapy (2.2–2.6 Gy/fraction) if radical radiation is envisaged [49]. Furthermore, advanced techniques may be used to allow delivery of differential prescription to primary target and nodes. Brachytherapy should be considered for boost in patients with response to external radiation [50]. Principles of systemic chemotherapy for vaginal melanoma should be the same as for vulvar melanomas in sections above.

5.5.7 Management of Recurrent Disease

Stage I and stage II lesions with central recurrence following previous radiation therapy might be salvaged with radical surgical procedures such as total vaginectomy, anterior or posterior exenteration or total pelvic exenteration. Likewise, early lesions that recur after limited surgical procedures could theoretically be salvaged with more radical surgical procedures or radiation therapy. Select patients who have undergone previous radiation may also be selected for re-irradiation. Patients not suitable for salvage local treatment should be considered for palliative chemotherapy and palliative care.

5.6 Summary

Radical radiotherapy and concurrent chemotherapy form the mainstay of treatment for vaginal cancers. Partial or total vaginectomy or extentration are feasible in patients either upfront or for salvage; however, they induce significant morbidity and impact on quality of life.

Gestational Trophoblastic Disease

Seema Gulia, Vikas Talreja, Jaya Ghosh, Sudeep Gupta,
and Jyoti Bajpai

Abbreviations

ActD	Actinomycin D
CM	Complete hydatidiform mole
CT	Computerized tomography
ETT	Epithelial trophoblastic tumor
GTD	Gestational trophoblastic disease
GTN	Gestational trophoblastic neoplasia
HM	Hydatidiform mole
LH	Luteinizing hormone
MRI	Magnetic resonance imaging
MTX	Methotrexate
PM	Partial hydatidiform mole
POC	Point of care
PSTT	Placental site trophoblastic tumor
TSH	Thyroid-stimulating hormone

1 Introduction

Gestational trophoblastic disease (GTD) encompasses a range of pregnancy-related disorders categorized by an autonomous overgrowth of fetal chorionic tissue or trophoblast that includes benign, premalignant disorders, complete (CM) and partial hydatidiform mole (PM); persistent, malignant disorders of invasive mole like choriocarcinoma, epithelial trophoblastic tumor (ETT) and placental site trophoblastic tumor (PSTT). Hydatidiform mole (HM) is the most common and benign subtype of the disease. The persistent/malignant forms of the disease are called gestational trophoblastic neoplasia (GTN) (Table 1).

Table 1 Classification of gestational trophoblastic disease (GTD)

Benign GTD	Malignant GTN (metastatic/nonmetastatic)
Partial mole	Invasive mole Choriocarcinoma
Complete mole	PSTT Epithelioid TT

2 Epidemiology

The incidence of GTD varies radically across the globe. The incidence is higher in Asian countries (3–10 times) compared to developed world [1, 2]. The incidence of molar pregnancy is 1 in 12/500 in Asia and Latin America and 1 in 500 in India. The incidence of GTD in various studies in India is variable and ranges between 1:190 and 1:650 deliveries. In another study by Ballal PK et al., the prevalence of GTD was 1.35 per 1000 births in a tertiary care center in Mangaluru, Karnataka, which is similar to the ones reported from northern India. The central India has reported slightly higher prevalence between 1.68 and 2.9 per 1000 deliveries [3].

After a molar pregnancy, the risk of recurrent complete and partial mole is around 1%–2% and the risk increases to 15%–20% after second molar gestation [4]. Some repeat molar gestations are due to familial or sporadic biparental molar disease which is an autosomal recessive disorder with mutations in NLRP7 (70% of cases) or KHDC3L (5% of cases) resulting in diploid complete moles [5].

About 50% cases of GTN ascend from molar pregnancy, 25% from miscarriages or tubal pregnancy and 25% from term or preterm pregnancy [6]. The incidence of GTN after spontaneous miscarriage is assessed at 1 in 15,000 pregnancies, and the incidence after a term pregnancy is around one per 150,000 pregnancies. The incidence of GTN following all types of pregnancies is around 1 in 40,000 pregnancies. Most (80%) of GTDs are hydatidiform moles, followed by 15% invasive moles and 5% choriocarcinomas (Table 2) [7].

Table 2 Major risk factors for developing GTN (Ref. [5])

• Prior molar pregnancy
• Advanced maternal age (>40 years)
• Asian, American Indian and African ancestry
In complete mole, postmolar GTN occurs more frequently [40%–50%] in patients with one or more high-risk features, including:
• Pre-evacuation uterine size larger than dates
• hCG levels >100,000 mIU/mL

3 Clinical Presentation

The patients commonly presents with vaginal bleeding (85%). Other clinical features like excessive uterine enlargement (50%), hyperemesis and rare presentations like anemia, early onset pre-eclampsia, abdominal distension and hyperthyroidism have become less common due to early diagnosis by ultrasound [8, 9]. Partial hydatidiform moles present with vaginal bleeding or missed or incomplete abortion. Partial moles grow slowly and present later than complete moles (usually at late first or early second trimester) [9]. Choriocarcinoma has an affinity for vascular invasion and may metastasize to lung (causing hemoptysis, pulmonary embolism), to brain (causing neurological symptoms, intracranial bleed), to abdomen (causing abdominal hemorrhage, abdominal distension). It may metastasize to vagina causing a bluish sub urethral nodule, which may bleed on touch. The most common sites of metastasis are lung (80%), followed by vagina (30%), brain (10%) and liver (10%). The lung metastasis develop first followed by liver and brain metastasis [10].

4 Imaging

The first investigation of choice is transvaginal or transabdominal ultrasound; however, transvaginal is preferred due to higher resolution and closeness to the study area. Ultrasound reveals an intrauterine mass of small vesicles, which are diffusely distributed within the uterine cavity, have variable echogenicity and are typically seen as "snow storm" and bunch of grapes" [11]. These vesicles have size varying from 1 to 30 mm and epitomize the hyperplastic and hydropic villi. In addition to an enlarged uterus, theca lutein ovarian cysts may be seen on imaging.

Computerized tomography: CT scan is used for detection of metastatic disease in liver and lung. The primary disease in the uterus is seen as focal irregular hypodense lesion with or without bilateral ovarian enlargement showing multiple theca lutein cysts [12].

Magnetic resonance imaging: MRI brain is recommended for patients who are either symptomatic for brain metastasis, in case of histopathological diagnosis of choriocarcinoma or in patients with extensive lung metastasis. MRI can be used to identify the depth of myometrial invasion and the parametrial extension of local disease [13].

5 Laboratory Evaluation

Beta hCG: Elevated beta hCG is the first sign of possibility of developing GTN. Serum beta hCG level should be the first investigation in all patients with suspected GTN, in women with history of molar pregnancy or with history of abortion, or with history of normal pregnancy and also in any woman of reproductive age who presents with metastatic disease with unknown site of primary disease.

Following evacuation of a complete or partial molar pregnancy, serial serum beta hCG levels are monitored on weekly basis, until an undetectable level is reached. The diagnosis of post molar GTN should be suspected if beta hCG levels start to rise or remain elevated over several weeks. The diagnosis of postmolar GTN is as per following FIGO criteria [14]:

1. Four values or more of βhCG plateau (±10%) over at least 3 weeks: days 0, 7, 14 and 21
2. A rise of βhCG of ≥10% for 3 values or more over at least 2 weeks: days 0, 7 and 14
3. Histologic diagnosis of choriocarcinoma
4. Persistence of βhCG beyond 6 months after mole evacuation

Any woman of reproductive age who presents with metastatic disease with unknown site of primary disease and elevated beta hCG should be managed as GTN. Biopsy of metastatic lesions is not advisable as it may lead to torrential hemorrhage.

5.1 Interpretation of Beta hCG Levels

Human chorionic gonadotropin is a glycoprotein hormone with an alpha subunit similar to luteinizing hormone (LH) and thyroid-stimulating hormone (TSH) and a specific beta subunit. The sensitivity of laboratory assays to detect the beta subunit has increased substantially over years [15].

Point of care (POC) tests have monoclonal antibodies or a combination of mono- and polyclonal antibodies, which spot the intact beta hCG in urine. POC tests can detect beta hCG between 15 and 100 mIU/mL [15].

5.1.1 Phantom hCG Syndrome

It is defined as persistent mild elevation of beta hCG in the absence of trophoblastic tissue. It is seen in 2% of women of reproductive age with persistent hCG values of <300 U/mL. It is due to the existence of nonspecific heterophile antibodies in the serum which bind the assay of IgG at sites common to humans and other species, and thus mimic hCG immunoactivity, thereby causing a false-positive result. However, these large heterophile antibodies are not excreted in urine. Thus, negative urinary tests for beta hCG can exclude false-positive serum hCG values due to heterophile antibodies. This is important to avoid unnecessary intervention after successful treatment for GTN and molar evacuation [16].

5.2 False-Positive hCG

Besides phantom hCG, false-positive hCG can be found in 1% of perimenopausal and 7% of postmenopausal women. These are due to increased levels of pituitary follicle-stimulating hormone and luteinizing hormone, and due to low level of pituitary hCG secretion. Oral contraceptives can be used to stop pituitary hCG secretion [16].

5.3 Quiescent GTN

It is defined as presence of low levels of beta hCG, without any clinical or radiological evidence of disease in patients with GTD. Usually the hCG level is around 50–100 mIU/mL and remains static for 3 months. The proposed mechanism is the secretion of low stable levels of hCG by slow-growing small focus of syncytiotrophoblast cells. In absence of cytotrophoblast, these are benign, do not progress to invasion or undergo malignant transformation and do not respond to either chemotherapy or surgery [16].

5.4 Hook Effect of hCG

This phenomenon is seen when hCG is in excess and point of care tests show false-negative result as dilution step is not performed to wash the excess hCG. These falsely low or negative results occur from oversaturation of the fixed, solid-phase antibody and of the free-floating labeled antibody, which prevents sandwich formation. To avoid this effect, the lab should be asked to perform a 1:1000 dilution, with which a correct value can be obtained [17].

6 Staging and Risk Stratification

The FIGO 2000 prognostic scoring system is used to decide the systemic therapy for GTN. This score predicts the risk of developing resistance to single-agent chemotherapy. Patients with score of 0–6 are called as low risk and with score of ≥7 are defined as high risk, which specifies the risk of developing resistance to therapy (Table 3) [18]. Anatomic FIGO staging is not used for prognosis, but it signifies uniform reporting all across the globe. (Table 4) [18]. The stage of disease is represented by a Roman numeral I, II, III or IV. The risk score is represented as Arabic numerals (2, 3…). PSTT and ETT are staged according to the FIGO classification, and the prognostic score is not used in these subtype of GTN.

Table 3 WHO risk scoring system based on prognostic factors [18]

Prognostic factors	0	1	2	4
Age (y)	<40	>40	–	–
Prior pregnancy	Mole	Abortion	Term	–
Interval (mo) from preceding pregnancy	<4	4–6	7–12	>12
Pretreatment serum hCG (mIU/mL)	10^3	10^3–10^4	10^4–10^5	>10^5
Largest tumor size including uterus size (cm)	–	3–5	>5	–
Site of metastasis	Lung	Spleen, kidney	GI tract	Brain, liver
Number of metastases	0	1–4	5–8	>8
Prior failed chemotherapy	–	–	Monotherapy	Combined therapy

Low-risk score—0–6; high-risk score ≥7

Table 4 FIGO staging of GTN [18]

Stage I	Disease limited to uterus
Stage II	Disease beyond the uterus, but is limited to genital structures (i.e., adnexa, vagina, broad ligament)
Stage III	Disease extends to lungs, with or without genital tract involvement
Stage IV	All other metastatic sites

7 Management of Molar Pregnancy

7.1 Uterine Evacuation

Suction curettage is the favored method for uterine evacuation, irrespective of uterine size [19]. During evacuation, mechanical dilation of the cervix should be performed rather than using prostaglandins for cervical ripening as later is associated with excessive bleeding. It is crucial to obtain a specimen for pathology evaluation to confirm the diagnosis of HM and to differentiate between a complete and partial mole. During suction evacuation, oxytocin infusion is to be started at the time of induction in order to enable myometrial contraction, and thus reduce the chances of blood loss.

Hysterectomy may be considered for women with hydatidiform mole who are ≥40 years and do not want fertility preservation. Hysterectomy prevents the development of local invasion, but it does not eradicate the risk of metastatic disease. Hence, beta hCG levels should be monitored to ensure that persistent neoplasia does not develop [20].

7.2 Follow-up

After evacuation, all patients should undergo serial serum beta hCG testing to assess for development of post molar GTN. American College of Obstetricians and Gynecologists advise the following protocol [21]: Serum hCG every week until nondetectable (<5 mIU/mL) for three consecutive weeks, then every month for 6 months.

7.3 Prophylactic Chemotherapy

Prophylactic chemotherapy is not routinely recommended for molar pregnancy. Evidence for its use comes from RCTs and one meta-analysis. In a meta-analysis reported in 2012 [22], including three randomized trials (n = 613 patients), prophylactic chemotherapy reduced the risk of GTN by 63% (relative risk [RR] 0.37, 95% CI 0.24–0.57). However, two studies included are of poor methodological quality, and when sensitivity analyses were done excluding these two studies, the benefit of prophylactic chemotherapy was lost (59 participants; RR 0.28; 95% CI 0.10 to 0.73; P = 0). Moreover, it was observed that patients who received prophylactic chemotherapy and were later developed GTN experienced a delay in succeeding diagnosis and required more chemotherapy cycles to achieve complete response. Therefore, prophylactic chemotherapy is not currently recommended, but it may be considered in women with complete mole who are at high risk of malignant transformation and are unreliable for follow-up (like adolescents or patients from poor socioeconomic class). Chemoprophylaxis has no impact on fertility [23]. Either methotrexate or actinomycin D can be used as chemoprophylaxis.

7.4 Contraception

Women with molar pregnancy must be advised to use barrier contraception during the entire interval of hCG monitoring because the pregnancy would hinder with follow-up testing of beta hCG level and would complicate management. An intrauterine device should not be used till the beta hCG levels are within normal range as there is high risk of uterine perforation due to subinvolution of the uterus. Barrier methods or hormonal contraception are preferred. Randomized trials have established the safety of post molar use of oral contraceptives. Gynecologic Oncology Group trial (n = 266) have evaluated the safety of oral contraceptives or barrier contraception after evacuation of hydatidiform mole [24]. Both the contraceptive measures were found to be equally effective. Moreover, a systematic review of seven studies (n = 1533) has also shown no increased risk of GTN with the use oral contraceptives after molar evacuation [25].

7.5 Future Pregnancy

The New England Trophoblastic Disease Center has reported obstetric outcomes from 1965 to 2013 [26], 1388 subsequent pregnancies were seen in cohort of patients with complete mole: 68.4% term live births, 7.4% premature deliveries, 0.5% stillbirths, 18.4% spontaneous abortions and 0.8% ectopic pregnancies. Major and minor congenital anomalies were detected in 3.8% infants. 357 subsequent pregnancies were seen in cohort of patients with partial mole: 72.8% term live births, 2.2% premature deliveries, 0.3% stillbirth, 17.9% spontaneous abortions and two (0.6%) ectopic pregnancies. Major and minor congenital anomalies were diagnosed in only 15% infants. Patients with molar pregnancies should expect similar reproductive outcomes as compared to the general population.

Recurrent molar pregnancy: The estimated risk of subsequent molar pregnancy: After one molar pregnancy is 1%–1.9% and after two molar pregnancies is 15%–17.5% [4].

8 Management of Low-Risk GTN

Low-risk GTN is characterized by modified WHO prognostic score of 6 or low. Majority of patients are cured with single-agent chemotherapy, either methotrexate or actinomycin D (ActD). Several different chemotherapy regimens have been used to treat low-risk GTN (Table 5). The response rates vary among protocol due to differences in drug dosages, routes of administration, schedules and number of chemotherapy cycles delivered after normalization of hCG. The weekly intramuscular or intermittent continuous intravenous infusion MTX regimens are less effective than the daily X 5 days MTX or 8-day alternating MTX/leucovorin regimens (as evident in Table 5); hence, the latter is the preferred regimen. The weekly intramuscular MTX regimen is not adequate, particularly in patients with WHO risk score of 5–6 and in patients with histopathological diagnosis of choriocarcinoma, as confirmed in the randomized trial comparing effectiveness weekly MTX with pulsed actinomycin [30], wherein the response rate was 9%.

Actinomycin D is generally used as a second-line therapy in patients who develop resistance to methotrexate. Tolerance to actinomycin D is poor and it is associated with higher toxicities (myelosuppression, nausea and alopecia) compared to

Table 5 Chemotherapy regimens for low-risk GTN

S. no	Agent used	Chemotherapy regimen	Primary response rates (CR) %
1	8-day alternating MTX and leucovorin [27, 28]	Inj Methotrexate 50 mg IM, days 1, 3, 5 and 7; leucovorin 15 mg orally, days 2, 4, 6 and 8; recycle every 14 days until hCG normal × 6 weeks. (at our Centre MTX dose is adjusted as per body weight to 1 mg/kg, T leucovorin continues to be given as 15 mg. Methotrexate may be given IV or IM)	69
2	Actinomycin D biweekly (pulse) [4]	1.25 mg/m^2 (maximum 2 mg) IV; recycle every 14 days until hCG normal × 3 weeks	70
3.	5 days Actinomycin D [28, 29]	5 days of ActD (12 μgm/kg or 0.5 mg intravenous) repeated every 14 days (at TMH we use this regimen and cap dose of Actinomycin D to 0.5 mg/day)	88

MTX. Actinomycin D is tolerated better when given in biweekly schedule, as in the study by Osborne et al. [30]. Another protocol for ActD administration is 5-day course of Actinomycin-D 12 mcg/kg or 0.5 mg intravenously every 2 weeks. There is no difference in outcome between the two regimens of ActD [31].

8.1 Methotrexate Versus Actinomycin D

Multiple trials have compared MTX and ActD regimens for treatment of low-risk GTN, including several randomized studies and a meta-analysis [30, 32, 33] The 2012 meta-analysis included five studies concluded that ActD was associated with significantly higher cure rates than MTX (relative risk 0.64, 95% CI 0.54–0.76) without differences in toxicity [33]. However, there was heterogeneity in this analysis due to the various schedules of MTX (as a weekly injection, five-day injection and the eight-day schedule) and ActD (bi-weekly pulsed IV and the five-day IV dosing) included, number of patients involves was less (n = 517). Hence, the efficacy of actinomycin over MTX cannot be confirmed based on this meta-analysis. Another trial published after the meta-analysis (n = 62) randomized patients with low-risk gestational trophoblastic disease to MTX or ActD found no difference in complete remission rates between MTX and ActD (78 and 80%, respectively). Moreover, frequency of adverse effects was similar between the two agents [28].

8.2 Monitoring

While on treatment, serum hCG levels should be monitored every week to determine response [29]. Once the serum hCG has normalized, 3 more cycles of chemotherapy are given as consolidation to reduce the chance of recurrence [29].

8.3 Management of Resistant Disease

Resistance to first-line therapy should be suspected if there is persistent elevation of beta hCG over 3 consecutive samples or an increase over 2 consecutive samples lasting >2 weeks [26]. If beta hCG levels are low (<100 IU/L), phantom hCG must be ruled out. Hysterectomy is considered if the tumor is confined to the uterus and the patient has completed the child bearing age. If fertility is desired, salvage chemotherapy is recommended. Patients who develop resistance to methotrexate and have low hCG levels (<300 IU/mL) should be treated with dactinomycin or vice versa if actinomycin is used in first-line setting. Patients who fail single-agent treatment and presents with higher levels of hCG (>300 IU/mL), such patients should receive combination EMA-CO chemotherapy [29].

9 Management of High-Risk GTN

These patients are commonly treated with combination chemotherapy regimens, as the risk of developing drug resistance is high if single-agent therapy is used. Various protocols have been used as shown in Table 6. EMACO [Day 1: actinomycin-D 0.5 mg iv, etoposide 100 mg/m^2 iv, methotrexate 300 mg/m^2 iv, Day 2: actinomycin-D 0.5 mg iv, etoposide 100 mg/m^2 iv, folinic acid 15 mg post 12 hourly for 4 doses, Day 8: vincristine 0.8 mg/m^2 (maximum 2 mg), cyclophosphamide 600 mg/m^2] is the preferred due to its high primary remission rates and lower toxicities compared to other regimens. EMACO is the most commonly used first-line chemotherapy protocol, as shown in 2013 Cochrane review but this regimen has not been compared to other chemotherapy protocols like MAC or FAV [39].

Treatment should be continued until the hCG level becomes undetectable and remains undetectable for three consecutive weeks. At least three courses of EMA-CO should be administered after the patient achieves beta hCG levels below 5 as consolidation therapy to diminish the risk of relapse and 4 cycles are given in case of brain and liver metastasis.

Table 6 Chemotherapy regimens for high-risk GTN

Study	Protocol	No. of patients	Primary remission rates	Toxicity/mortality
Kim et al. 1998 [34]	EMA/CO (96) MA (49) MAC (40) CHAMOCA (42)	227	EMA/CO: 91%; MA: 63%; MAC: 68%; CHAMOCA: 76%	EMA/CO: 9%; MA: 36%; MAC: 32%; CHAMOCA: 22%
Bower et al. 1998 [35]	EMAC/CO	272	78%	4%
Fulop et al. 2012 [36]	EMA/CO (26) MAC (118) BEP (17)	174	EMA/CO: 81%; MAC: 93% BEP: 94%	–
Gulia et al. 2014 [37]	EMACO	22	73%	13%
Chauhan et al. 2010 [38]	EMACO	78	66%	–

9.1 Salvage Therapy

Most of the patients with GTN are cured with standard therapy; 20%–25% of high-risk patients develop resistant disease. Different platinum-based regimens should be considered in such cases. Common regimens are EMA-EP (omitting day 2 etoposide and dactinomycin and alternating weekly with etoposide and cisplatin); TE/TP (paclitaxel and etoposide alternating weekly with paclitaxel and cisplatin); ACE (dactinomycin, cisplatin and etoposide); VIP (etoposide, ifosfamide and cisplatin); BEP (bleomycin, etoposide and cisplatin); cisplatin, vincristine and methotrexate; PVB (cisplatin, vinblastine and bleomycin); ICE (high-dose ifosfamide, carboplatin and etoposide); and combinations with gemcitabine or capecitabine [38]. Response rate to second-line therapy varies from 20% to 75%, EMA /EP being the most common regimen with cure rates up to 70% [40]. Surgical resection of resistant foci of disease is important in salvage of these patients. In one series, 24 patients with high-risk metastatic resistant GTN undergoing surgical resection had cure rates of 84% [41]. Surgical procedures included hysterectomy, pulmonary resection and small bowel resection.

10 Early Mortality

Early mortality is defined as death that occurs within 4 weeks of treatment initiation. Causes of early mortality are: uncontrolled hemorrhage of highly vascularized tumors and metastases, massive pulmonary embolism, tumor lysis syndrome, sepsis secondary to chemotherapy [42, 43]. Early deaths in high-risk GTN (extensive pulmonary, hepatic and brain metastasis; FIGO score more than 12; and/or major bleeding) can be reduced by use of low-dose chemotherapy initially; etoposide (100 mg/m^2) and cisplatin (20 mg/m^2) on days 1 and 2 every week for one or two courses as shown by Charing Cross group. Use of low-dose EP has reduced early mortality from 7.3% to 0.7%. The gradual decrease in tumor volume lessens the risk of hemorrhage in vital organs and thus the mortality. Moreover, use of EP induction therapy did not increase the risk of resistance to further EMA/CO chemotherapy [44].

Vaginal hemorrhage: Significant bleeding needs urgent attention and support with blood products is to be continued until resolution. Embolization, hysterectomy and arterial ligation may be required as deferring measures till chemotherapy controls the disease, but death is very rare due to extensive vaginal bleeding [45].

11 CNS Metastasis

Initial treatment with low-dose etoposide and cisplatin is recommended to be repeated every week for 2–3 cycles. Dexamethasone is added to decrease brain r edema, and there is no role of prophylactic antiepileptic drugs. Modified EMA-CO chemotherapy is administered once patient is stabilized. The dose of methotrexate (in modified EMACO) is escalated to 1 g/m^2 over 24 h. The higher dose of MTX allows for adequate levels of MTX within the cerebrospinal fluid. Intrathecal MTX 12.5 mg is given on day 8. Modified EMACO with intrathecal MTX (without WBRT) has resulted in remission in 85% of cases [46]. Some centers use whole brain radiotherapy (3000 cGY over 10 fractions); it reduces the risk of intracranial bleeding. But there is no evidence that whole brain radiotherapy improves survival [47]. Intrathecal MTX is not given with WBRT to avoid toxicities (leukoencephalopathy).

In presence of very high-risk disease (WHO score ≥13, liver metastases along with brain metastases), EMA-EP may be considered. Inpatients with brain metastasis, the dose of methotrexate is increased to 1 g/m^2 and day 2 of etoposide and dactinomycin are omitted from the EMAEP regimen. Intrathecal methotrexate is given with the EP on day 8 [46].

12 Role of Surgery in GTN

The advent of chemotherapy and individualized protocols has made GTN a highly curable disease, surgery still plays important role in management of these cases.

1. Molar pregnancy. Suction curettage is the preferred method of uterine evacuation. Prophylactic hysterectomy may be considered for patients more than 40 years of age who are not desirous of future child bearing. Hysterectomy reduces the risk of local invasion but does not eliminate the risk of metastatic disease that can happen in 3.5% of cases [19].
2. GTN. Hysterectomy is indicated for excessive uncontrolled vaginal bleeding not amenable to uterine artery embolization or medical measures, as initial therapy in low-risk GTN when disease is limited to uterus and there is no desire to conceive in the future.
3. Surgery in chemo-resistant disease/relapsed GTN.
   (a) Hysterectomy is an option in patients who did not respond to first-line and second-line therapy and have bulk of disease limited to uterus.
   (b) Segmental uterine resection can be considered in patients with small disease (<2 cm), low hCG level and desirous of future pregnancy [48].
   (c) Pulmonary resection is the most commonly performed procedure to eliminate extra uterine metastatic disease. Best outcome seen in patients with single unilateral lesion, hCG less than 1000 IU/mL, controlled uterine disease, absence of other metastatic sites and good performance status [49].

13 Placental Site Trophoblastic Tumor

Placental site trophoblastic tumor (PSTT) is a rare form of GTN, incidence in the population is approximately 1/100,000 pregnancies constituting 1%–2% of all types of GTN [50].It is usually confined to uterus at presentation. Common site of metastasis includes vagina, lung and brain [51]. The level of serum beta hCG in PSTT does not correlate with tumor burden, hence not useful for diagnosis, treatment or follow-up. FIGO scoring is not used to determine the treatment of PSTT; hysterectomy is the preferred treatment for patients with nonmetastatic disease. Unlike choriocarcinoma, PSTT is comparatively resistant to chemotherapy. Patients with metastatic or recurrent disease are treated with combination chemotherapy EMA/CO or EMA/EP. Extra uterine spread of disease and antecedent pregnancy interval more than 4 years are poor prognostic factors [51]. The mortality rate in PSTT is 10%–20% [52].

Epithelioid trophoblastic tumors is the rarest of all GTN. Patients have moderately elevated—β-hCG (median, 665 IU/L). The common site of presentation is lower uterine segment and these tumors can be misdiagnosed as squamous cell carcinoma. The most common site of metastasis is lung. These tumors are also resistant to chemotherapy like PSTT. The only significant prognostic factor for ETT is FIGO stage. [51, 52].

14 Surveillance

14.1 Molar Pregnancy

After evacuation, weekly serum beta hCG level should be monitored until 3 consecutive weekly assays are normal. Subsequently, beta hCG levels should be checked at monthly interval for 6 months. Contraception is recommended for 6 months.

All patients with GTN are followed with weekly hCG values until undetectable for 3 consecutive weeks, and then monthly until undetectable for 12 months. For high-risk GTN some center's recommended monitoring for 2 years.

14.2 Contraception

Intrauterine device should not be used because of potential for uterine perforation. Barrier methods are preferred. Oral contraceptives are safe to use after normalization of serum β-hCG.

15 Future Pregnancy

Fertility is not affected by either single-agent or combination (EMA-CO) chemotherapy for GTN. The pregnancy rate is more than 83% after either treatment [53]. Only one study has shown slight increase in stillbirth in pregnancies post GTN chemotherapy, other studies have found no increase in abortions, stillbirths, preterm labor or congenital anomalies.

Patients with prior molar pregnancy or GTN are advised to have a first trimester ultrasound to confirm normal gestation in subsequent pregnancies. Serum hCG is measured at 6 weeks after delivery to exclude GTN. After preterm or term deliveries or after abortion in patients with prior molar pregnancy or GTN, the placenta should be carefully examined and sent for histopathological evaluation if any abnormalities are seen [54].

GTD and GTN are almost always curable as these diseases are extremely sensitive to chemotherapy drugs (except rare histologies) and presence of a highly sensitive biomarker (beta hCG), serial measurement of which has enabled early recognition of resistance or relapse so that the subsequent

Table 7 Prognosis of GTN

GTN	5 years OS	Ref.
Low-risk GTN	100%	[41]
High-risk GTN	88%–94%	[43]
PSTT		[51]
Stage I	171.3 months	
Stage II–III	70 months	
Stage IV	9.5 months	

lines of therapies can be initiated before significant tumor regrowth has occurred (Table 7).

16 Long-Term Toxicities

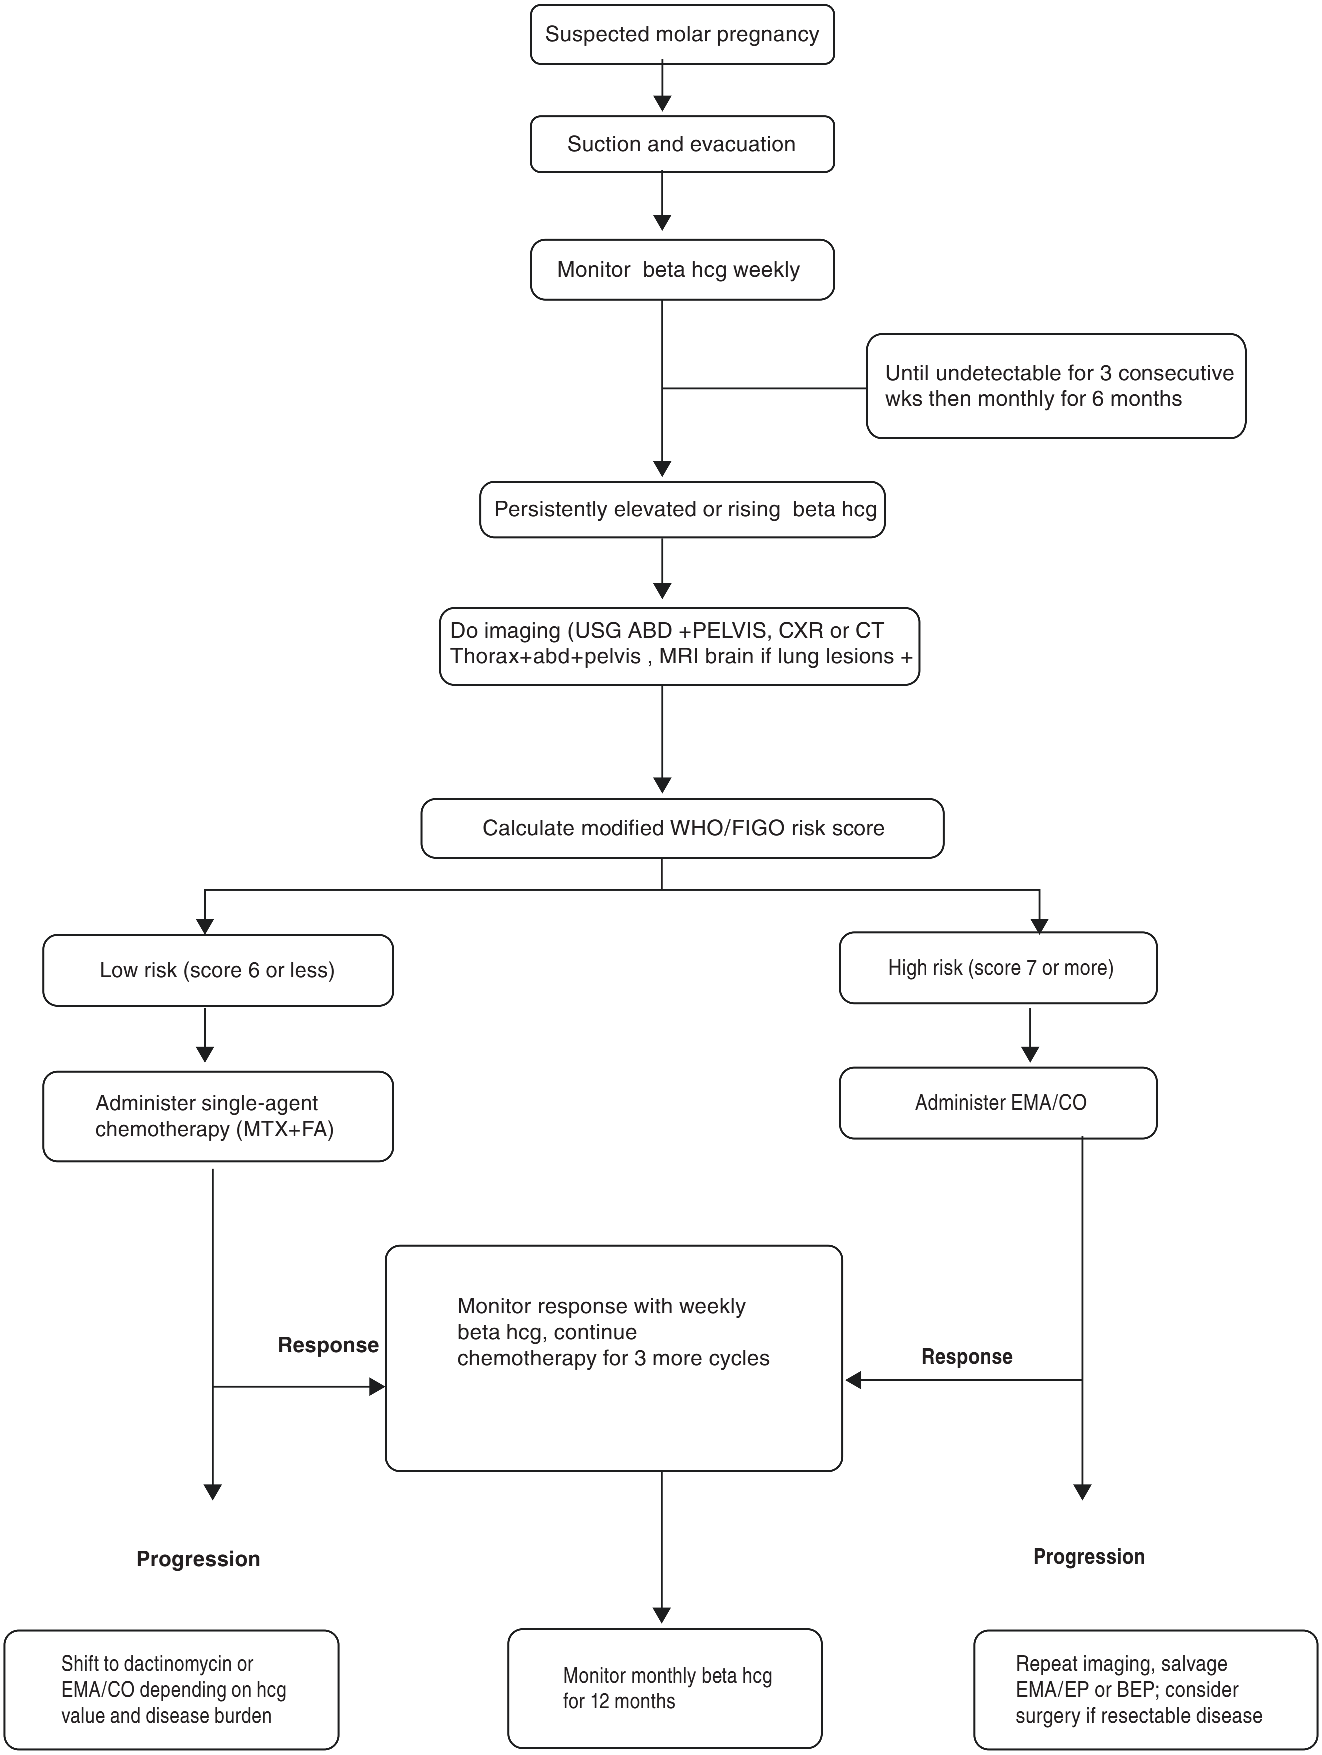
GTN being a highly curable disease, the key component of management is minimization of any long-term side effects. The recent study (comprising 32,244 person-years of follow-up of 1903 patients with GTDs), shows no overall increased risk of second malignancies following MTX or EMACO (if treatment duration of EMACO is less than 6 months). Patients treated with EMA-CO or with alkylating agents or cisplatin in other regimen have increased risk of second malignancies especially leukemia, oral and pharyngeal cancers, melanoma and meningioma. EMA-CO also induces menopause 3 years earlier than anticipated [55].

17 Psychosocial Issues

Women with GTN may experience anxiety, mood disturbance, sexual problems and fears over future fertility. Patient needs assessments, counseling and psychological interventions both during treatment and after remission is achieved [56].

18 Tata Memorial Centre Experience

At our center we are following the standard guidelines for the management of GTN cases (Fig. 1). Patients with low-risk GTN are treated with SA MTX at 1 mg/kg given IV on days 1, 3, 5 and 7 with oral leucovorin 15 mg single dose on days 2, 4, 6 and 8. The cycle is repeated every 2 weeks. Serum b-hCG levels are measured every week, plus before the start of every chemotherapy cycle; drug resistance is defined as any two static or one increasing value on treatment. Based on the beta hCG value patients are treated with either actinomycin D or multiagent chemotherapy. EMA/CO. Patients with high-risk GTN are started on the EMA/CO regimen. Patients who do not respond to the EMA/CO regimen are treated with EMA/EP or BEP regimens. Patients undergo hysterectomy only if there is no response to chemotherapy or if there is intractable bleeding which is not controlled by medical measures. Treatment is continued until



Suspected molar pregnancy
Suction and evacuation
Monitor beta hcg weekly
Until undetectable for 3 consecutive wks then monthly for 6 months
Persistently elevated or rising beta hcg
Do imaging (USG ABD +PELVIS, CXR or CT Thorax+abd+pelvis , MRI brain if lung lesions +
Calculate modified WHO/FIGO risk score
Low risk (score 6 or less)
High risk (score 7 or more)
Administer single-agent chemotherapy (MTX+FA)
Administer EMA/CO
Response
Monitor response with weekly beta hcg, continue chemotherapy for 3 more cycles
Response
Progression
Progression
Shift to dactinomycin or EMA/CO depending on hcg value and disease burden
Monitor monthly beta hcg for 12 months
Repeat imaging, salvage EMA/EP or BEP; consider surgery if resectable disease

Fig. 1 Algorithm for management of gestational trophoblastic disease

b-hCG values are normal (<5 IU/L) till three consecutive chemotherapy cycles. After the last chemotherapy cycle, patients are kept on follow-up with b-hCG monitoring consistent with standard guideline and advised contraceptive measures. Our published results are comparable to international standards [37].

19 Summary and Key Points for Management of GTN

Gestational trophoblastic disease is a disease with highest prevalence in Asian subcontinent and importantly affects young women with major implications to the families and nation as a whole. If treated adequately, there is an impressive cure rate. Hence, the future management strategies for GTDs should strategically incorporate fertility preservation as standard of care.

19.1 Diagnosis

- Reproductive-age women with either molar pregnancy or abnormal bleeding or unexplained metastatic disease: serum quantitative hCG assessment should be done [IV, A]
- Once diagnosed with GTN: patients should undergo beta hCG level, pelvic US and chest X-ray [IV, A]
- Nonmolar pregnancy or with suspicion of lung metastases in chest X-ray: CT scan chest and an MRI of the brain should be done [IV, A]

19.2 Staging

- After molar pregnancies and choriocarcinoma: FIGO scoring system should be used; [IV, A]

19.3 Treatment

- Hydatidiform mole (HM): sonographic guided suction and curettage is the essential first step of treatment.
- Indications for chemotherapy following the diagnosis of GTD:
  - Persistent or rising hCG after evacuation or
  - Histologically confirmed choriocarcinoma or
  - Distant metastasis (brain, liver or gastrointestinal tract or, lung metastasis [2 cm] or
  - Serum hCG level > 20,000 IU/l, 4 weeks after evacuation (risk of uterine perforation) or heavy vaginal bleeding or any intraperitoneal or gastrointestinal hemorrhage

19.3.1 Low-Risk Disease

- Single-agent CT (**preferred first-line regimen is MTX with FA rescue**): CT should be continued for 6 weeks after hCG normalization [II, A].
- A primary hysterectomy may be considered for perimenopausal patients with no desire to preserve fertility

19.3.2 High-Risk Disease

- MultiagentCT [IV, A]: **EMACO** is the preferred option. In patients with FIGO score >13, low-dose induction “EP” can be used to reduce the early morality [IV, A]

19.3.3 Resistant or Recurrent GTN

- Salvage therapy is effective in majority of cases.
- Surgical resection may cure the patients with solitary disease site. All other cases should be treated with cisplatin-based chemotherapy regimens like EMA/EP or TE/TP [IV, A]

19.4 Follow-Up

19.4.1 During Treatment

- Weekly serum hCG monitoring until 3 consecutive normal levels [IV, A]
- Thereafter, once a month serum hCG monitoring, for 12 months in low-risk and for 18 months in high-risk disease,
- Then 6 monthly for 1 year in low-risk and 24 months in high-risk patients,
- Then annually until 5 years [IV, A]
- No follow-up imaging tests are required [IV, A]

Epithelial Ovarian Cancer

Jaya Ghosh, Amita Maheshwari, Bharat Rekhi,
Palak Bhavesh Thakkar (Popat), Anuja Damani,
Pabashi Poddar, and Umesh Mahantshetty

1 Introduction

Ovarian cancer is among the top ten cancers affecting women around the world. Its incidence (age standardized rates) varies from per 5–9/100, 000 women in less to more developed parts of the world [1]. Its incidence in India is 4–6 per 100,000 in most states [2]. The most common subtype of ovarian cancer is epithelial ovarian cancer (90%), followed by germ cell tumors (5%) and the sex cord stromal tumors (3%–5%) [3, 4]. The common symptoms of epithelial ovarian cancers at presentation are dyspepsia, bloating, abdominal distension, and pain in abdomen, which are largely nonspecific and hence most patients with high-grade epithelial ovarian cancers are diagnosed in advanced stages across global boundaries and succumb to their disease [1]. Screening is not effective as it has not shown any significant reduction in mortality [5]. There is a common International Federation of Gynecology and Obstetrics (FIGO) staging system for all subtypes of ovarian cancer (Table 1—FIGO) and is the strongest predictor of outcome [6]. The management of ovarian cancers is multimodal with surgery and chemotherapy being

Table 1 FIGO 2014 staging of ovarian cancer

Stage I	Tumor confined to ovaries or fallopian tube(s) IA: Tumor limited to one ovary (capsule intact) or fallopian tube; no tumor on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings IB: Tumor limited to both ovaries (capsules intact) or fallopian tubes; no tumor on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings IC: Tumor limited to one or both ovaries or fallopian tubes, with any of the following: IC1: Surgical spill IC2: Capsule ruptured before surgery or tumor on ovarian or fallopian tube surface IC3: Malignant cells in the ascites or peritoneal washings Dense adhesions with histologically proven tumor cells justify upgrading to stage II
Stage II	Tumor involves one or both ovaries or fallopian tubes with pelvic extension (below pelvic brim) or primary peritoneal cancer IIA: Extension and/or implants on uterus and/or fallopian tubes and/or ovaries IIB: Extension to other pelvic intraperitoneal tissues
Stage III	Tumor involves one or both ovaries or fallopian tubes, or primary peritoneal cancer, with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes IIIA1: Positive retroperitoneal lymph nodes only (cytologically or histologically proven): IIIA1(i) Metastasis up to 10 mm in greatest dimension IIIA1(ii) Metastasis more than 10 mm in greatest dimension IIIA2: Microscopic extra pelvic (above the pelvic brim) peritoneal involvement with or without positive retroperitoneal lymph nodes IIB: Macroscopic peritoneal metastasis beyond the pelvis up to 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes IIIC: Macroscopic peritoneal metastasis beyond the pelvis more than 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes (includes extension of tumor to capsule of liver and spleen without parenchymal involvement of either organ)
Stage IV	Distant metastasis excluding Stage IVA: Pleural effusion with positive cytology Stage IVB: Parenchymal metastases and metastases to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

the mainstay of treatment with vital inputs from radiology and pathology for diagnosis, staging, and subtyping of tumor [3]. Radiotherapy has a limited role in the management of ovarian cancers [7]. Early integration of palliative care is needed especially in the management of advanced high-grade epithelial ovarian cancers [8]. Survivorship and fertility issues also need to be addressed in young patients with early-stage low-grade epithelial ovarian cancers [4].

2 Risk Factors

Genetic predisposition is one of the strongest risk predictors for ovarian cancer [9]. The cumulative risk of ovarian cancer up to the age 80 is 44% for BRCA 1 mutation and 17% for BRCA 2 mutation [10]. Risk reducing salpingo-oophorectomy reduces the risk of ovarian cancer by 70%–85% and also reduces mortality [11]. It should be preferable be done around 35–40 years of age after completion of family [12].

One of the hypotheses for risk of epithelial ovarian cancer is “incessant ovulation” leading to repeated trauma, repair, and thus mutations of the ovarian surface [9, 13]. Hence, factors such as increased parity and oral contraceptive use, which (give rest to) ovulation, are associated with reduced risk, while late menopause (after 50 years), hormone replacement therapy, and higher body mass index are associated with increased risk [14–16]. Tubal ligation has also been shown to have a protective effect possibly due to the fimbrial origin of ovarian cancer and distancing of the fimbria from ovarian surface by ligation [16–18]. Recently, it has been studied that these hormonal and reproductive factors and endometriosis are more commonly associated with nonserous histology like endometroid and clear cell carcinoma than serous histology [17].

3 Evaluation and Work-up

The various subtypes of ovarian cancers have different age of presentation. In women less than 40 years, the common tumors are germ cell tumors, borderline tumors, low-grade epithelial ovarian cancers, and sex cord stromal tumors. In those older than 40 years of age, high-grade epithelial ovarian cancers are most common [19]. Rarely, lymphomas, small cell carcinoma, and Ewing’s tumor are also reported [20]. A major diagnostic pitfall is metastasis to the ovary (Krukenberg) mimicking a primary ovarian tumor. The common sites of origin being stomach, colon, gall bladder, and lobular breast cancers [21]. In India, tuberculosis is also a great mimicker [22]. Hence, a careful history and a good clinical examination remain the cornerstone of evaluation. Diagnostic work-up includes an ultrasonography which may be done for initial evaluation followed by a contrast-enhanced computer tomography (CT) scan of the abdomen and pelvis for staging [23]. Tumor markers to be done depend on age at presentation. In patients presenting with disease limited to the ovary which is suspicious of malignancy, a surgical evaluation needs to be done. It is important not to biopsy the ovarian mass in early-stage disease as it would upstage the tumor. In patients with advanced disease, an ascitic fluid cytology is done to obtain a diagnosis. If cytology is nondiagnostic or there is no ascites, a CT-guided biopsy of the omental nodule, other metastatic site or the pelvic mass may be done in advanced disease.

3.1 Tumor Markers

3.1.1 CA 125

This has limited sensitivity and is not a specific marker of epithelial ovarian cancer. Any peritoneal irritation causes the CA 125 levels to rise. Hence, it may be raised even up to thousands in other malignancies (including Krukenberg tumor) or even in germ cell tumors. It may also be very high in abdominal tuberculosis or endometriosis. Hence, only high CA 125 cannot be diagnostic of epithelial ovarian cancer. Also, in some epithelial cancers like low-grade serous, mucinous and clear cell tumors CA 125 may not be raised [24].

3.1.2 CEA

It is important to do CEA levels in those with ovarian masses or ascites to rule out primary gastro-intestinal tumors. CA 125: CEA levels >25 is suggestive of primary ovarian origin [25].

3.1.3 CA 19.9

It is not mandatory to do CA 19.9 in patients with suspected ovarian cancer. However, it is important to know that it may be raised both in case of pancreato-biliary tumors as well as mucinous carcinoma of ovary [26, 27].

3.1.4 Germ Cell Tumor Markers

Alpha feto protein AFP, β HCG, S. LDH (lactate dehydrogenase).

Germ cell tumor markers should be done in women under the age of 40 years with suspected ovarian neoplasm. This is so as not to miss these highly curable malignancies. It is important to note that in young patients presenting with ascites and high CA 125 with cytology showing adenocarcinoma, it is important to still do germ cell tumor markers as it is sometimes difficult to distinguish germ cell tumors and epithelial ovarian cancers on cytology and CA125 may be high in both.

3.2 Endoscopy

In patients presenting with bilateral solid ovarian masses or those with ascites without ovarian masses, a gastrointestinal primary (GI) primary should be ruled out. An upper GI endoscopy and in those with high CEA a lower GI endoscopy should be done before making a diagnosis of primary peritoneal carcinoma in a patient presenting with ascites and no ovarian mass.

3.3 Radiology: Imaging of Ovarian Malignancies

The common imaging modalities for suspected ovarian neoplasm are ultrasonography (USG) for characterization of ovarian masses and contrast-enhanced CT scan for overall staging and detecting presence of hemorrhage and calcification. Magnetic resonance imaging (MRI) is occasionally used to better characterize ovarian masses and is usually more specific in excluding a lesion as benign, rather than the histotype of the malignant lesions.

3.3.1 USG of Abdomen and Pelvis

On USG, ovarian lesions may be seen as simple (anechoic) cysts, complicated (moving internal echoes), hemorrhagic (classical fish-net appearance), or complex (solid-cystic or with papillary projections). Doppler examination may help in assessment of vascularity of a solid lesion. Ovarian metastases (Krukenberg's tumor) usually present as bilateral solid masses. Commonest primaries are stomach, breast, gall bladder, colon, or lung.

On USG, a risk of malignancy index (RMI) score can be calculated [28]. More than 200 score is used for referring a patient to a specialized gynae-oncologist, and for supplementary MRI imaging.

$$\mathrm{RMI} = U \times M \times \mathrm{CA125}$$

*U*ltrasound (U) is based on: multilocular cysts, solid areas, metastases, ascites, and bilateral lesions. $U = 0$ (for 0 abnormality), $U = 1$ (for 1 abnormality), $U = 4$ (for 2–5 abnormalities).

Menopausal status is scored as 1 = pre-menopausal and 4 = post-menopausal

Serum CA125 is the value in IU/mL.

In a lady detected with ovarian cysts on ultrasonography, a decision to follow-up versus further evaluation varies on her calculated risk factors. A simple cyst is followed up in a low-risk woman, if it measures 5–7 cm, while in a high-risk woman, a more than 2 cm nonresolving cyst warrants follow-up assessment. A hemorrhagic cyst from 3 to 5 cm is followed at 3 monthly intervals.

3.3.2 MRI of Abdomen and Pelvis

Further assessment of USG detected findings, better predictability of benign and locoregional staging may be performed on an MRI [29]. Suspicious features on MRI are enhancing septae and solid-enhancing internal components, nodules, and projections. Locoregional adenopathy, omental, and peritoneal disease is also well seen.

3.3.3 CECT of Abdomen and Pelvis (±Thorax)

It is done at baseline for staging of ovarian malignancy (Fig. 1). It helps in better assessment of thoracic and abdominal disease, serosal and omental nodules, and adenopathy. It is also useful for response assessment in patients on chemotherapy. Response may be seen as a decrease in the size adnexal masses or a decrease in the extent of its enhancing walls, septations or mural nodular projections and a decrease in the size and number of omental caking, deposits and ascites may also be seen. Less commonly progression on chemotherapy may be seen. Response is evaluated based on RECIST 1.1 (Response Evaluation Criteria in Solid Tumors 1.1) [30]. A correlation with CA125 is a good surrogate marker for response assessment, if the levels are raised in the initial disease, and has been defined by Gynecological Cancer Intergroup (GCIG) [31].

3.3.4 Chest X-Ray

This is done at baseline to assess for any pleural effusion.

3.3.5 Mammography

In those patients presenting with only ascites, a bilateral mammogram to rule out a breast primary needs to be done, as rarely lobular carcinomas of the breast may present with ascites.

3.4 Pathological Diagnosis

3.4.1 Cytology

A vast majority of epithelial ovarian cancers, especially high-grade serous type, present with ascites. An accurate assessment of ascitic fluid sample, for detection of cancer cells, is crucial to initiate neoadjuvant chemotherapy (Fig. 2). Cell block preparations are useful to test various immunohistochemical markers to differentiate mesothelial cells from adenocarcinoma and subtype an adenocarcinoma, including of different types and grades (Fig. 3a, b) [32, 33].

The other indications of cytology in cases of ovarian malignancies include aspiration from a recurrent lesion, an accessible solid lesion, or metastatic lesions.

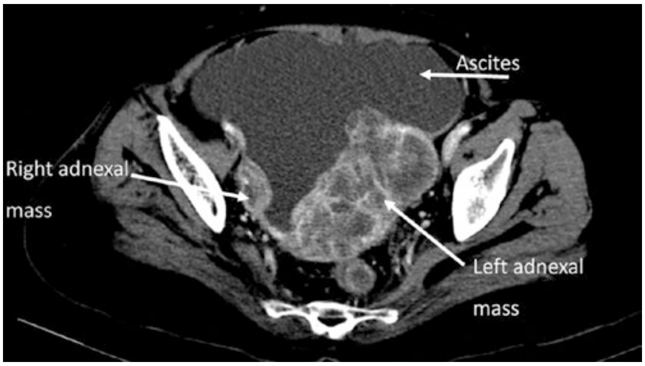

Fig. 1 Bilateral ovarian masses (left larger than right), showing heterogenous solid and cystic component, with prominent enhancing septations

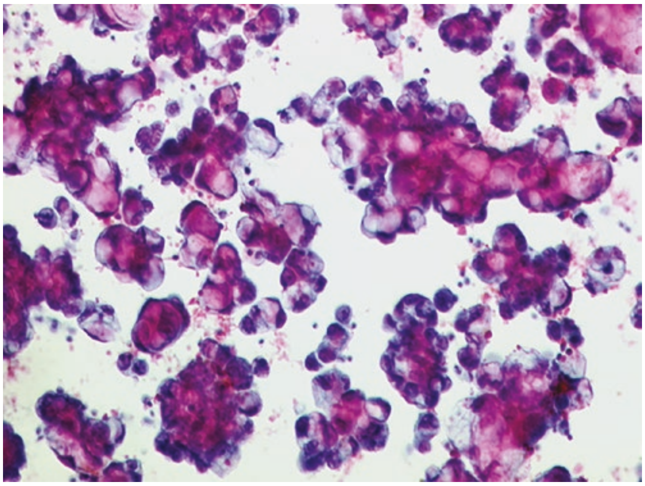

Fig. 2 Smear from ascitic fluid sample displaying several clusters of malignant cells in a case of carcinoma ovary. Papanicolaou (Pap) ×200

3.4.2 Biopsy

Image-guided biopsy is useful in planning management for women with suspected ovarian cancer. It is useful in providing a site-specific tumor diagnosis in 93% of cases. It helps in diagnosis especially in cases presenting with ovarian masses without ascites, or when there is a strong clinico-radiological suspicion of malignancy but the ascitic fluid is negative of malignancy. It is also useful in differentiating primary epithelial ovarian cancer from metastasis which might mimic it for example from breast, GI tract, etc. In patients with advanced ovarian cancer who have poor response to neoadjuvant chemotherapy, it is important to biopsy from the adnexal masses before planning second-line chemotherapy to detect any metastasis or low-grade tumors. Moreover, it is useful in situations of diagnostic uncertainty, e.g., unusual imaging patterns of disease such as peritoneal carcinoma with bilateral solid ovarian masses [34].

Inset: immunohistochemical staining showing PAX8 (marker of Mullerian differentiation) positivity in the tumor cells. Diaminobenzidine (DAB), ×400

3.5 Genetic Clinic Referrals

The present ASCO guidelines recommend germline genetic testing for all epithelial ovarian cancers [35]. Although high-grade serous carcinomas are most commonly found to have BRCA 1and 2 mutations, other histologies like low-grade serous, endometroid, clear cell, and carcinosarcomas have also been found to have these mutations [35]. Germline BRCA1 and 2 mutations are found in around 13% to 15% of all ovarian cancers. Mucinous tumors of the ovary rarely have any mutations in BRCA and hence testing it is not recommended in this group. However, around 20% may have mutations resulting in mismatch repair deficiency (dMMR) [35]. Thus, testing for dMMR is recommended in mucinous tumors and also in clear cell and endometroid subtype [35]. In a recent Indian study, the incidence of pathogenic germline BRCA 1 or 2 mutation was found in 21% of ovarian and primary peritoneal cancers [36]. Among these 67% did not have family history [36]. Hence though ideally all patients should undergo germline testing, if resource constraints are present then at least those with a family history and those younger than 50 years (median age in India) should undergo testing.

4 Pathology

Ovarian tumors are classified on histopathology, based upon World Health Organization (WHO) classification, broadly into epithelial, sex cord-stromal, germ cell, germ cell sex cord stromal, hematolymphoid, and secondary tumors. Epithelial ovarian tumors are further classified as benign, borderline/atypical proliferative, and malignant [20].

4.1 Molecular Classification of Epithelial Ovarian Cancer

A "dualistic theory" is proposed for development of epithelial ovarian epithelial cancers, i.e., a distinct pathway for development of type I and type II tumors.

Type I tumors are a mixed bag which comprising of low-grade serous carcinoma, low-grade endometroid, clear cell, and mucinous subtypes (Figs. 4 and 5). Low-grade serous adenocarcinomas are characterized by the *Kras-Braf*-mediated signal transduction pathway [37]. The same genetic

mechanism underlines borderline serous ovarian tumors, from which low-grade serous carcinomas develop. Low-grade mucinous tumors are also associated with mutations in the Kras pathway [37]. The clear cell type is characterized by *PIK3CA* and *ARID1A* mutations [38–40]. In addition, alterations of genes encoding β-catenin (e.g., *CTNNB1, CDKN2A*), *PIK3CA,* and *PTEN* have also been reported in type I endometrioid serous tumors and clear cell tumors, in various studies [41–43]. Furthermore, presence of specific mutations can have an impact on treatment [39, 44].

Type II tumors are mainly composed of high-grade serous (Fig. 6), others being high-grade endometroid, carcinosarcoma, and undifferentiated carcinomas. Underlying *p53* mutation drives more than 95% of high-grade serous carcinomas [37, 38]. Inactivation of *BRCA1* and 2 genes either by mutation or inactivation of expression by promoter methylation are seen in nearly 45% of cases.

Thus, the low-grade and high-grade ovarian cancers have distinct pathways of development and usually low-grade tumors do not progress to high grade [37].

Integrated genomic analysis has led to a greater understanding of high-grade serous carcinoma and mechanisms of resistance [45, 46]. The four TCGA subtypes differentiated, immunoreactive, mesenchymal, and proliferative have different survival outcomes [45]. The differentiated and immunoreactive subtypes have better outcomes than mesenchymal and proliferative. The proliferative subtype has shown survival benefit with the addition of bevacizumab (anti angiogenic) to chemotherapy [47]. Thus, the different subtypes would hopefully also provide better understanding of the

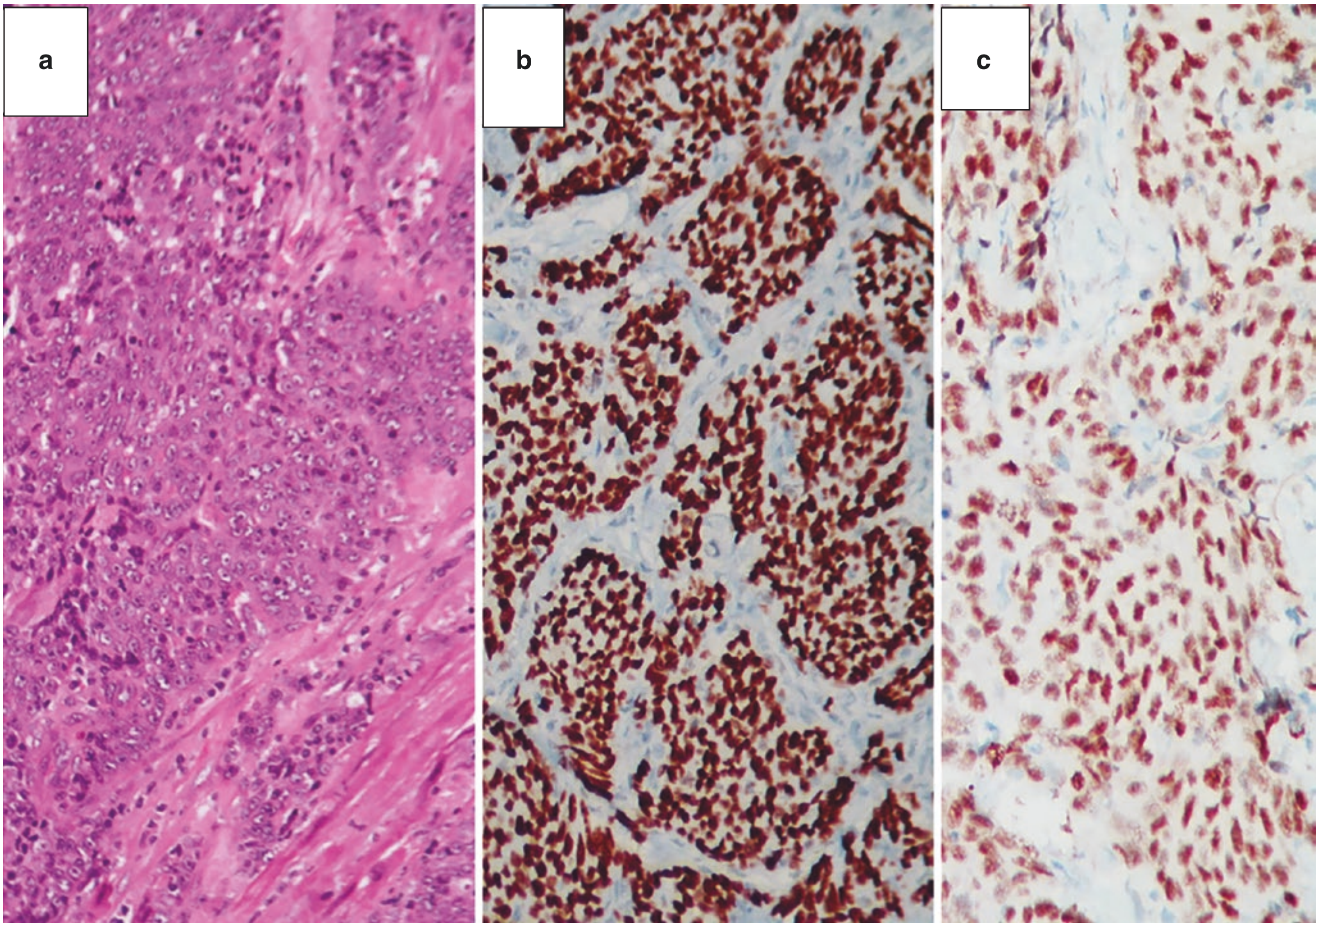

Fig. 6 (**a**) High-grade serous adenocarcinoma. H and E, ×200. (**b**) Diffuse, intense intranuclear p53 positivity, indicative of p53 mutation. (**c**) Intranuclear WT1 positivity, reinforcing serous subtype in this case

likelihood of benefit from different targeted therapy and immunotherapy in future.

There is also greater understanding of mucinous tumors of the ovary [48, 49]. Once Krukenberg tumor has been excluded, primary mucinous tumors of the ovary have now been classified into expansile and the more aggressive infiltrative subtypes which have been integrated into therapeutic decision making [3, 48]. While Kras mutation is found in all mucinous tumors, the more aggressive subtype has p53 mutations [48]. HER 2 amplification and MSI (microsatellite instability) in some of these tumors may provide a possible therapeutic target [48]. Thus, an understanding of the biology would provide a better insight on treatment strategy.

5 Borderline Ovarian Tumors

Borderline ovarian tumors (BOTs) constitute around 15%–20% of all epithelial tumors [50]. As the name suggests BOT are tumors which do not have any ovarian stromal invasion and are thus different from carcinomas which invade the stroma. They are therefore of low malignant potential and were previously called "semi malignant" [51]. Peritoneal disease present in BOT is referred to as "implants" [51]. The term borderline is based on the pathology of the primary ovarian tumor. Thus, borderline ovarian tumors may be associated with noninvasive or invasive implants (i.e., peritoneal, or omental implants invading its surrounding stroma). Serous borderline tumors of the ovary with invasive peritoneal implants are considered as low-grade serous carcinoma [3, 51].

An expert pathologist and extensive sectioning of ovarian tumor during frozen section and final histopathological reporting are important for a correct diagnosis of BOTs. Absent stromal invasion is the principal diagnostic criterion for BOTs but micro-invasion may be seen cut off (5 mm) [20, 52]. Another important pathological feature is the presence of micropapillary pattern which confers a poor prognosis and an increased risk of invasive carcinoma [51]. BOT are subdivided into serous, mucinous, endometrioid, clear cell, transitional cell, and mixed epithelial cell BOTs. Serous BOTs (67%) and mucinous (30%) BOTs are the most common subtypes. Peritoneal implants can be either invasive or noninvasive; noninvasive implants are common and share similar characteristics as primary BOT, whereas invasive implants show features like infiltrating adenocarcinomas and are considered as low-grade carcinoma. Invasive implants are most commonly seen with serous BOTs (~30%) and rarely with mucinous BOTs (3%–4%) [53, 54]. The presence of lymph node implants does not confer a worse prognosis [51].

BOT occur in younger women (a decade earlier) than epithelial ovarian cancers. They are difficult to diagnose preoperatively using radiological methods or tumor markers like CA 125 which may be raised even in borderline tumors [3, 51].

Surgery is the mainstay of treatment for BOTs. Complete staging includes complete inspection and palpation, cytology, resection of all suspicious tissue, bilateral salpingo-oophorectomy, total hysterectomy, omentectomy, and multiple peritoneal biopsies [52, 53]. The role of hysterectomy and lymphadenectomy is still controversial and may be avoided. Degree of residual disease is the most important prognostic factor in BOTs and has been studied in the ROBOT study (The Retrospective Multicenter Outcome Survey in Borderline Tumors) [55]. Fertility preserving surgeries involving preserving one ovary and uterus may be offered in young patients desirous of fertility. There is an increased risk of recurrence (especially > IA) and needs to be discussed before surgery [3]. The overall survival is, however, not different as most recurrences are borderline [3, 51] and can be salvaged. In women who have been incompletely staged with an incidental diagnosis of BOTs after surgery, role of restaging is still debated. It may be considered in those who have had only a cystectomy and on pathology there is micropapillary pattern or microinvasion or incomplete excision of peritoneal implants [56, 57].

Adjuvant chemotherapy is not indicated in BOT irrespective of stage or lymph node involvement or presence of micropapillary pattern [3, 51–53].

In borderline ovarian tumor with invasive implants, however, the role of adjuvant chemotherapy is debated. Though this group of tumors have a higher rate of recurrence (around 40%) and has now been termed as low-grade serous carcinoma, these are two distinct entities [51, 58]. Though not chemo-sensitive, the response rate to chemotherapy in patients with advanced stage is reported around 60% [58, 59]. The role of adjuvant chemotherapy is unclear, the current consensus favors observation [3, 60]. However, in patients with advanced stage, with residual disease and invasive implants adjuvant chemotherapy is an option.

They have an excellent 5- and 10-year survival rates (97%–99% and 70%–95%) in contrast to their malignant counterparts but late recurrences (15%–20%) may occur especially in serous BOTs. These patients therefore need long-term follow-up. They may recur either as BOTs (70%–80%) or as invasive carcinoma (20%–30%). Complete cytoreductive surgery with complete excision of all visible disease forms the mainstay of treatment even in recurrences [53, 61, 62].

Thus, the mainstay of treatment of BOT is surgery which achieves long-term cure in most patients.

6 Epithelial Ovarian Cancer

6.1 Principles of Management

Surgery and chemotherapy are the mainstays of management in epithelial ovarian cancers. Ovarian cancer is not one disease as already discussed and though today most subtypes are treated similarly this may change in future. Hence, it is important to note the subtype of the cancer when available. The stage of cancer is based on The FIGO 2014 classification (Table 1). Early-stage ovarian cancers undergo primary debulking surgery followed by adjuvant chemotherapy where indicated. Advanced stage ovarian cancers can undergo either neoadjuvant chemotherapy (NACT) followed by interval debulking surgery and adjuvant chemotherapy or primary debulking surgery followed by adjuvant chemotherapy (Fig. 7). There is less surgical morbidity with equivalent results for both progression-free and overall survival with the use of NACT compared to adjuvant. Hence, in patients with advanced ovarian cancers especially in those with pleural effusion, poor performance status, and low albumin neo adjuvant chemotherapy is preferred.

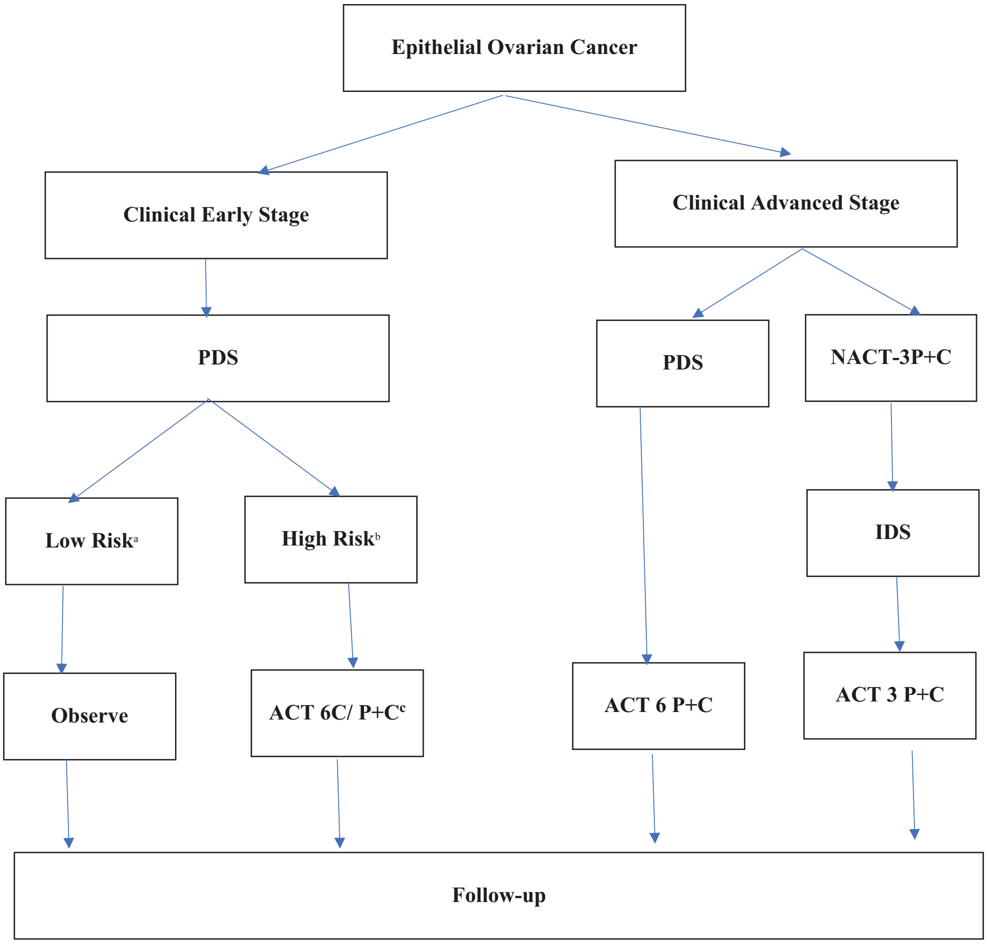
6.2 Surgical Management

Surgery plays an important role in management of all phases of ovarian cancer. Surgery may be required for histological diagnosis, stage determination, cytoreduction in primary and recurrent settings, symptom relief, and palliation of bowel symptoms (Table 2).

6.2.1 Principles of Surgical Staging for Ovarian Cancer

Surgery for ovarian cancer requires experienced and skillful surgeon with understanding of pattern of disease spread. The surgeon should take into consideration patient's wish for future fertility and histological subtype of ovarian cancer. Laparotomy is the standard surgical approach. Minimal access surgery for surgical staging of early ovarian cancer is experimental and should not be offered outside a clinical trial.

Laparotomy with a vertical incision is recommended. Incision must be adequate to evaluate the entire abdominal



[a] Early Stage Low Risk – Stage IA/IB, Grade 1, non-clear cell histology

[b] Early Stage High Risk – Stage IA/IB, Grade 2/3, clear cell histology, Stage IC, Stage II

[c] Six cycles single-agent carboplatin OR paclitaxel and carboplatin (may consider either single-agent C or 3 cycles P+C in non-serous histology)

Fig. 7 Management of epithelial ovarian cancer algorithm

Table 2 Terminology for common surgical procedure used in cancer ovary

Staging surgery—surgery performed in clinically early-stage disease to know the extent of disease.

Primary cytoreductive surgery/primary debulking—initial surgery to establish stage, diagnosis, and maximal tumor debulking before initiation of chemotherapy in patients with advanced disease.

Interval cytoreductive surgery/interval debulking surgery—cytoreductive surgery after neoadjuvant chemotherapy (after biopsy or after suboptimal surgery).

Secondary cytoreductive surgery—surgery in patients with recurrent ovarian cancer after complete primary treatment, which includes primary surgery with or without chemotherapy, and a disease-free interval.

Palliative surgery—surgery performed to relieve symptoms.

cavity. On opening the abdominal cavity if free peritoneal fluid is found, it should be collected for cytology after estimating the amount. In case fluid is not present, liberal peritoneal washings should be collected from pelvis, paracolic gutters, and subdiaphragmatic area. Careful inspection and palpation of all peritoneal surfaces including diaphragm, paracolic gutter, bladder and cul-de sac peritoneum, serosa and mesentery of bowel, and retroperitoneum should be done and documented.

All effort should be made to remove the ovarian mass intact as rupture of ovarian lesion will lead to upstaging of disease. Bilateral salpingo-oophorectomy and hysterectomy should be performed. For patient desiring fertility, unilateral salpingo-oophorectomy or bilateral salpingo-oophorectomy with preservation of uterus can be done in selected cases with early invasive epithelial ovarian cancer and borderline tumors. Availability of intraoperative frozen section is an important tool in intraoperative management of these patients. It provides information regarding nature of ovarian mass and histological subtype and thereby assists in deciding the extent of surgery. At our center, frozen section is routinely used for intraoperative evaluation of suspicious adnexal masses. In a retrospective evaluation of 217 patients with suspected ovarian neoplasms who underwent primary surgery at our institution, frozen section showed sensitivity of 100%, 93.5%, and 45.5% for benign, malignant, and borderline tumors, respectively. The corresponding specificities were 93.2%, 98.3%, and 98.5%. The overall accuracy of frozen section diagnosis was 91.2%. The majority of cases of disagreements were in the mucinous and borderline tumors [63].

Omentum should be removed as part of staging surgery. Any suspicious lesion should be excised and sent separately for histopathological examination. Random, multiple peritoneal biopsies from cul-de-sac, right and left pelvic side walls, and right and left paracolic gutters and under-surface of diaphragm should be taken if there is no gross disease seen beyond ovaries. Bilateral pelvic and para-aortic lymph node dissection is recommended in early stage though no benefit proven in advanced stages. A randomized trial comparing systematic lymphadenectomy with lymph node sampling in patients with epithelial ovarian cancer macroscopically confined to the pelvis showed that systematic lymphadenectomy led to upstaging of disease in 13% of patients [64].

6.2.2 Surgery for Early Ovarian Cancer

A large majority of early ovarian cancer patients present as "suspicious adnexal mass" on pre-surgery work-up. The purpose of surgery for suspected ovarian cancer is to establish the diagnosis, to accurately stage the disease and to select patients for adjuvant treatment. Optimal staging of early ovarian cancer may lead to upstaging of disease in approximately 30% cases [65]. Staging surgery is indicated for all ovarian cancer patients including borderline tumors.

6.2.3 Surgery for Advanced Ovarian Cancer

Surgery plays an important role in the management of ovarian cancer even with widespread disease. Surgical debulking is technically feasible in majority patients with ovarian cancers because spread of cancer cells follows peritoneal borders of abdominal cavity without deep invasion.

Primary Debulking Surgery

Primary debulking is the cornerstone in surgical management of advanced ovarian cancer, but it has survival advantage only when it leads to optimal cytoreduction, i.e., nil, or minimal residual disease (Table 3). The most important prognostic factor under control of operating surgeon is the amount of residual disease at the end of cytoreductive surgery. Therefore, every effort should be made to remove all gross disease from all sites and achieve optimal cytoreduction (nil or minimal gross residual disease). Patients with advanced ovarian cancer with low volume disease should undergo complete cytoreduction with hysterectomy, bilateral salpingo-oophorectomy with infra-gastric omentectomy between hepatic flexure and splenic hilum. Suspicious and enlarged nodes should be resected. However, systemic pelvic and paraaortic lymph node dissection does not offer survival benefit in patients with advanced ovarian cancer who do not have clinically suspicious nodes [66].

Table 3 Terminology used for completeness of surgery for ovarian cancer

R0 resection—Complete removal of all visible tumors to no macroscopic residual disease
R1 resection—Minimal residual macroscopic disease with individual tumor size ≤1 cm
R2 resection—Suboptimal debulking surgery—gross residual disease resulting in macroscopic disease >1 cm

In patients with high-volume disease procedures that may be required for optimal cytoreduction may include bowel resection, appendectomy, stripping of diaphragm and peritoneal surface, splenectomy, partial cystectomy, partial hepatectomy wedge gastrectomy, and distal pancreatectomy. Extensive involvement of upper abdomen may hinder optimal debulking of tumor hence aggressive upper abdominal surgery should be performed only when entire tumor can be removed with acceptable morbidity. Minimal access surgery may help in evaluating feasibility of optimal cytoreduction in patients with newly diagnosed ovarian cancer. For selected patients, placement of intraperitoneal catheter can be done at the time of initial surgery for adjuvant intraperitoneal chemotherapy.

Patients who are not suitable for upfront cytoreduction should be treated with neoadjuvant chemotherapy. Table 4 shows important factors that may favor neoadjuvant chemotherapy over upfront cytoreductive surgery for patients with advanced ovarian cancer. In patients with stage IIIC disease with omental metastasis of less than 5 cm primary debulking surgery may be considered [67].

Interval Debulking Surgery (IDS)

Neoadjuvant chemotherapy followed by interval debulking surgery (IDS) is an alternative treatment approach for patients with advanced ovarian cancer where upfront surgery is not feasible or unlikely to result in optimal cytoreduction. Surgery is generally done after 3 or 4 cycles of neoadjuvant chemotherapy. Total abdominal hysterectomy with bilateral salpingo-oophorectomy and omentectomy with excision of all

Table 4 Factors in favor of neoadjuvant chemotherapy in advanced ovarian cancer

Disease related *Unlikely to achieve optimal cytoreduction*	**Patient related**	**Availability of Infrastructure**
• Stage IVB disease • Bulky upper abdominal disease • Extensive peritoneal carcinomatosis • Extensive bowel wall involvement requiring >1.5 m of bowel resection or multiple bowel resections are anticipated • Disease at porta hepatis/superior mesentric artery • Disease at root of small bowel mesentery	• ECOG PS ≥2 • Elderly • Low albumin • Recent venous thromboembolism • Recent myocardial infarction • Multiple medical comorbidities	• Surgical expertise • Anesthesia and intensive care facilities • Interventional radiologist

visible disease should be done to achieve complete cytoreduction during IDS procedure. In a randomized phase III trial conducted by the European Organization for the Research and Treatment of Cancer (EORTC) interval cytoreduction after neoadjuvant chemotherapy for advanced ovarian cancer has shown similar survivals compared to primary cytoreduction and adjuvant chemotherapy with fewer peri-operative complications. The rate of optimal cytoreduction was 41.6% after primary surgery and 80.6% after interval surgery. There was higher postoperative deaths, infection, hemorrhage and venous complications with upfront surgery [25]. Another phase III multicenter trial (CHORUS) showed similar results with significantly higher postsurgical morbidity and mortality in upfront surgery arm without any survival advantage [68]. In our experience, optimal cytoreduction rate in patients with advanced disease after neoadjuvant chemotherapy is 81.5% with acceptable perioperative morbidity. The rates of Grade 3 or 4 intraoperative and postoperative complications were quite acceptable, 4% each. The median progression-free survival was (PFS) was 15 months and the median overall survival (OS) was 35 months in these patients [69].

Thus, the decision for neoadjuvant chemotherapy in advanced ovarian cancers is based on patient and tumor characteristics.

6.3 Medical Management

6.3.1 Principles of Systemic Therapy

Platinum-based chemotherapy has long remained the backbone of treatment of ovarian cancer. There is greater understanding now of the reason for the same. Although 15% of patients have germline BRCA mutation, around 51% have a defect in the homologous DNA repair pathway (BRCA ness) [45]. Thus, the ovarian cancer cells cannot repair the DNA damage (adducts) caused by platinum leading to cell death. This is the reason for increased sensitivity to platinum and longer survival in EOC patients with BRCA mutation [70]. This BRCA ness of ovarian cancer cells is also the reason for their response to PARP inhibitors which inhibits DNA repair [71]. Antiangiogenic agents also play a key role [72]. Greater understanding of tumor biology would help in better selection of drugs.

Chemotherapy

Among the chemotherapeutic drugs, carboplatin and paclitaxel continue to form the backbone and will be discussed in detail.

Carboplatin. Carboplatin and cisplatin are platinum compounds which act by causing DNA adducts. They have equal efficacy in ovarian cancer; however, carboplatin is preferred due to ease of administration and less emetogenicity and nephrotoxicity [73]. It is important to note that unlike many chemotherapeutic drugs, platinum is not a substrate for multidrug resistance protein (MDR1), which causes drug efflux out of the cell [74]. Another unique feature of carboplatin is the delayed hypersensitivity which generally occurs after a median of 8 cycles in about one-third of patients [75]. This is because there is exposure to low levels of free platinum in each cycle which causes sensitization and subsequent retreatment leads to a type I hypersensitivity reaction [75, 76]. Thus, one should be alert to this possibility with repeated platinum use and inform patients regarding its symptoms [76]. In those with mild reaction carboplatin may be continued with anti-allergic medications those with more severe reaction need discontinuation of carboplatin [77]. Though there are desensitization protocols [78], their use in routine clinical practice is difficult. Cisplatin may be used in those with carboplatin hypersensitivity with close monitoring [77]. In life-threatening reactions, however, no platinum should be re-challenged [76]. Use with liposomal doxorubicin reduces the incidence of hypersensitivity reaction possibly because of masking of antigenic sites by pegylation [79]. Although prolonged infusions have been associated with less hypersensitivity [76], prophylactic prolonged infusions have not shown to reduce the incidence in randomized trials with use of premedication [80].

Carboplatin is excreted almost completely by the kidneys [81]. The dosing is thus based on the area under the curve (AUC) of plasma concentration versus time which in turn depends on the renal clearance of the drug and thus affected by the glomerular filtration rate (GFR) [82]. This is done by using the Calvert formula, total dose in mg = AUC × (GFR +25) where 25 is a constant to account for the nonrenal clearance of the tissue bound carboplatin [82, 83]. Creatinine clearance is taken as a surrogate for GFR and is usually calculated by the Cockcroft-Gault formula [84]. However, it is important to remember that serum creatinine is also affected by diet, body composition and tubular secretion [84]. Thus, this formula may overestimate or underestimate GFR in those at extremes of age and body surface area, low serum albumin [84]. Thus, the estimated creatinine clearance should be capped at 125 mL/min [85]. For those with very low serum creatinine especially in elderly and cachectic patients a minimum s creatinine of 0.7 should be used [85]. In patients with single kidney or underlying medical renal disease a measured GFR using DTPA GFR may be considered.

Paclitaxel. Paclitaxel is the other backbone of treatment of ovarian cancer. It was derived from the bark of the pacific Yew tree, Taxus Brevifolia, hence the name taxane [86]. Today, though, there is a total synthesis of this natural product with growing demand [86]. Paclitaxel stabilizes microtubule and thus prevents spindle formation during metaphase ultimately leading to cell death, another mechanism being multipolar division [86]. It is highly albumin bound (95%) and mainly cleared by hepatic metabolism by cytochrome P450 isozyme CYP2C and CYP3A, with less than 10% renal clearance [87]. Thus, care needs to be taken in patients with hypoalbuminemia and with concomitant inducers/inhibitors of CYP3A. Since it is not soluble in water, solvent cremaphor EL is used. This is the primary cause of hypersensitivity with paclitaxel. Cremaphor leaches di-2-ethylhexyl phthalate (DEHP) plasticizer from PVC (polyvinyl chloride) bottles [88]. Hence, non-PVC bottles (glass, polypropylene) along with an inline filter is needed. Premedication with H1 and H2 blockers, dexamethasone and chlorpheniramine reduces the incidence of hypersensitivity to less than 10% [89], although severe anaphylaxis may still occur in 2%–4%. It causes joint pains and myalgias and it is important to prescribe analgesics preemptively. It may rarely cause cardiac bradyarrhythmia [89]. Apart from myelosuppression and alopecia, the other unique side effect is peripheral neuropathy which typically is the glove and stocking type. This is caused by axonal degeneration and demyelination and is contributed by both paclitaxel and cremaphor. It is dependent on dose and duration of infusion. Incidence of grade II-IV neuropathy is around 18% with 3 weekly paclitaxel and 26% with weekly paclitaxel [90]. Importantly, around half of survivors continue to experience some neuropathic symptoms [91].

The doublet of paclitaxel and carboplatin is usually given 3 times weekly. Paclitaxel is given before carboplatin. This is because in early pharmacokinetic studies it has been shown that there is 25% reduced clearance of paclitaxel if cisplatin is given before paclitaxel [92]. The hypothesis that a weekly dose dense regimen would improve survival was not proven to be true (ICON 8, Mito 7) except in one study (JGOG 3016) [93–95]. Weekly regimens are also associated with more myelosuppression [93]. Thus, the 3 times weekly regimen continues to remain the standard of care.

Antiangiogenic Agents

Angiogenesis plays a critical role in the development and spread of ovarian cancer [72]. VEGF expression leads to leaky peritoneal vessel and ascites [72]. Bevacizumab a humanized monoclonal antibody against VEGF has a therapeutic role in ovarian cancers. The main side effects being hypertension, proteinuria, thromboembolic events, bowel perforation especially in those who have received more than three lines of therapy, have bowel wall involvement or obstruction [96]. Thus, a careful work-up and patient selection needs to be done before initiating bevacizumab.

PARP Inhibitors

PARP (poly adenosine diphosphate [ADP]–ribose polymerase) repairs DNA damage by base excision repair. In cells which have a defect in the homologous repair pathway like BRCA, PARP inhibition would lead to cell death by "synthetic lethality" as both DNA repair mechanisms would be defunct [71]. Several different PARP inhibitors like olaparib, niraparib, and rucaparib are available. The main side effects of these are myelosuppression, fatigue, gastrointestinal, especially nausea, diarrhea, dyspepsia, raised creatinine (olaparib, rucaparib), transaminitis (rucaparib), and hypertension (niraparib) and rare side effects (occurring in less than 2%) like myelodysplastic syndrome and pneumonitis [97]. Platinum sensitivity is a marker for PARP sensitivity [98]. There can be reversion of germline BRCA 1 and 2 alleles leading to resistance to PARP inhibitors [46] and have thus provided a significant addition in the armamentarium of ovarian cancer.

Immunotherapy

Unlike other cancers immunotherapy is yet to find a place in ovarian cancer. Recent trials in recurrent ovarian cancer with high PDL1 expression, CPS score (combined positive score calculated by the percentage of PDL1 positive cells, tumor cells, lymphocytes and macrophages to total viable tumor cells) greater than 10% have shown to have response rates of 18%, PFS of 2 months and OS of 24 months even in patients who have received 3–5 lines of prior therapy with a platinum-free interval of more than 3 months [99]. More needs to be explored in this direction.

6.3.2 Early-Stage Ovarian Cancer

In early-stage ovarian cancer, it is important to determine the indication for adjuvant chemotherapy, number of cycles, and whether to use a doublet or a single agent. Patients with stage IA or IB low-grade ovarian cancers can be observed after surgery alone. The high-risk early stage, IA/ B high grade, I C, II all grades, and clear cell carcinoma any stage would benefit from adjuvant chemotherapy [100]. The five-year overall survival is improved from 65% to 76% with the addition of adjuvant chemotherapy (ACTION/ICON 1trials)

[100]. Around 60% of these patients had received single-agent platinum [100]. When using a doublet with paclitaxel and carboplatin, there was no difference in overall survival with use of three or six cycles (GOG 157) [101]; however, subgroup analysis showed a benefit in those with serous histology [102]. Thus, in most early-stage ovarian cancers who need adjuvant chemotherapy, six cycles of single-agent carboplatin alone can be considered, though three or six cycles of paclitaxel and carboplatin are also options. In those with high-grade serous cancers, six cycles of paclitaxel and carboplatin should be considered.

6.3.3 Advanced Stage Ovarian Cancer

In advanced stage ovarian cancers, six cycles of paclitaxel and carboplatin remain the standard of care. This can be given either as six cycles of adjuvant or three cycles of neoadjuvant chemotherapy (NACT) followed by interval debulking surgery and three cycles of adjuvant chemotherapy. Long-term pooled analysis of the EORTC and CHORUS trials have proven the noninferiority of NACT compared to primary debulking surgery (PDS) with reduced perioperative morbidity in the NACT arm [67]. In stage IIIC disease, the median PFS of 12 months and OS of 30 months is similar in both the arms [67]. A subset of these patients with extra pelvic disease less than 5 cm had improved PFS (27 vs. 17 months) and OS (47 vs. 39 months) with upfront PDS [67]. In those with stage IV disease, the use of NACT has improved the median PFS (10.6 vs. 9.7 months) and OS (24 vs. 21 months) [67]. It is interesting to note that unlike other solid tumors, in patients with ovarian cancers with pleural effusion, which is a stage IV disease, interval debulking surgery is still done if there is a response to chemotherapy. Paclitaxel and carboplatin are the standard chemotherapy; however, single-agent carboplatin can also be considered, especially in those with poor performance status, low albumin, and elderly patients. Once the performance status and albumin improve, paclitaxel can be added. Docetaxel or liposomal doxorubicin with carboplatin are other options, especially in situations where paclitaxel cannot be used because of either hypersensitivity reaction or underlying neuropathy.

It is important to bear in mind that Krukenberg tumor or tuberculosis may at times mimic advanced ovarian cancer. Hence, a thorough history, clinical examination including breast examination, evaluation of supraclavicular lymph nodes needs to be done. Tumor marker ratio of CA125 to CEA should be greater than 25 [25] and there must be at least a cytological diagnosis. Those with a ratio of less than 25 or odd features like bilateral solid ovarian masses should undergo a biopsy and GI endoscopy. A histopathological diagnosis (image guided biopsy) would help to better delineate the subtype such as low-grade cancers which have low response to chemotherapy [103] and would benefit from upfront surgery and rule out Krukenberg. There is a change in diagnosis in about 3% of patients [25]. Initial response to chemotherapy is seen in 60–80% patients [3]. In those patients who do not have a response to NACT, it is again important to do a biopsy to know the histopathology (low grade, Krukenberg) before considering them as platinum refractory. There are presently no standard guidelines on management of patients with no or poor response to NACT. Change of chemotherapy may be considered (e.g., to liposomal doxorubicin) [104]. Around 70% of them would eventually relapse and the 5-year overall survival is 30% [1]. The possibility of cure in advanced ovarian cancer thus remains unlikely as of date but remains a distant dream.

Several attempts have been made to improve upon this survival. Among chemotherapy, the addition of a third drug has not improved survival [105]. The use of weekly schedule also did not show an improved survival despite initial promise [93, 95]. Two approaches which have shown promise are the use of intraperitoneal chemotherapy and maintenance therapy with bevacizumab or PARP inhibitors.

Intraperitoneal Chemotherapy

Ovarian cancer has this unique feature of recurring repeatedly in the peritoneal cavity, which provides a sanctuary site [106]. Thus, the rationale of delivering chemotherapy into the peritoneal cavity where it would achieve a higher concentration, almost 20 times for cisplatin and 1000 times for paclitaxel, compared to plasma [106]. In patients with stage III ovarian cancer with residual disease less than 1 cm after primary cytoreductive surgery, intraperitoneal (IP) chemotherapy with cisplatin and paclitaxel compared to intravenous (IV) chemotherapy has shown improved overall survival from 51 to 62 months even after 10 years of follow up [106, 107]. However, because of toxicities such as catheter-related infection, higher incidence of myelosuppression, gastrointestinal toxicity and neuropathy only about 40% are able to complete all chemotherapy [107]. Thus, in spite of improved survival IP chemotherapy has not had a widespread acceptance. Also, the recent results of another randomized trial of IP versus IV chemotherapy where both arms received dose dense paclitaxel and bevacizumab did not show any significant difference in the two arms [108].

Hyperthermic Intraperitoneal Chemotherapy

The rationale for using hyperthermia in (HIPEC) is the increased penetration of chemotherapy with hyperthermia, formation of DNA adducts, protein denaturation, activation of heat shock protein which are receptors for natural killer cells leading to cytotoxicity [109]. HIPEC after IDS has shown an improvement in both PFS (14 vs. 11 months) and OS (46 vs. 34 months); however, no benefit in PFS or OS was seen when it was performed after primary cytoreduction [109, 110]. Thus, several questions about HIPEC still remain unanswered, and it is presently still not the standard of care in first line ovarian cancer as per the ESMO ESGO guidelines, while it can be an option in patients undergoing IDS as per NCCN [3, 111–113]. Thus, the debate continues. Proper patient selection with respect to both surgical and medical fitness to receive the intraperitoneal cisplatin needs to be considered. It will be important in the future to identify subgroups who might benefit from HIPEC [111].

Maintenance Strategies

As most advanced ovarian cancers relapse, it was thought that maintenance therapy may help prevent a relapse. One of the first drugs to be used was paclitaxel (175 mg/m^2 q 28 days) rationale being the killing of slowly growing cells in the cell cycle and its anti-angiogenic effect [114]. Though in a randomized phase III study 12 months of maintenance compared to 3 months did improve PFS (28 vs. 21 months), residual neuropathy was significantly more (23% vs 13%) [114]. Thus, maintenance paclitaxel is not routinely used. Subsequently, bevacizumab and now PARP inhibitors have been used as maintenance and have shown improvement in PFS.

Bevacizumab. Two large, randomized trials of maintenance bevacizumab, the ICON 7 and GOG 218 proved a PFS benefit of its use in patients with advanced ovarian cancer [115, 116]. In the GOG 218 in patients with stage III and IV epithelial ovarian cancer, bevacizumab was added in the adjuvant setting with standard chemotherapy with six cycles of paclitaxel and carboplatin, starting from cycle 2 and continued until cycle 22 at 15 mg/kg [115]. Compared to the control arm of no bevacizumab, an improvement in PFS was seen (14 vs. 10 months) but no improvement in overall survival [115]. Another arm in which bevacizumab was used only during chemotherapy did not show any benefit in PFS or OS. In the ICON 7, bevacizumab at dose of 7.5 mg/kg was given with adjuvant chemotherapy for 5–6 cycles and continued for another 12 cycles in patients with high-risk early stage and advanced epithelial ovarian cancer [116]. In the overall population compared to the control arm of no bevacizumab though an initial PFS benefit was seen (19 vs. 17.3 months), this was not statistically significant on longer follow up and there was no OS benefit [117]. Only in the high-risk subgroup (stage IV disease, stage III disease with suboptimal cytoreduction or inoperable) disease was a benefit seen in PFS (16 vs 10.5 months) and OS (39.7 versus 30.3 months) with bevacizumab in the long-term follow-up [117]. Also, it is associated with increased toxicity of hypertension grade II or higher in 18%–23%, thromboembolic events 7% and GI wall disruption seen in 2.8% [115, 116]. Bevacizumab is approved in the adjuvant setting. However, the magnitude of benefit, toxicity and costs needs to be weighed and discussed with the patient and may be considered in high-risk patients.

PARP Inhibitors. PARP inhibitors olaparib and niraparib have been approved as first-line maintenance therapy in advanced stage (FIGO III and IV) ovarian cancer [118, 119]. In the SOLO1 trial, patients with either germline or somatic BRCA 1 or 2 mutation, with stage III /IV high-grade serous, endometroid ovarian, fallopian tube of primary peritoneal cancer who have had a complete or partial response after platinum-based chemotherapy (they also underwent primary or interval debulking surgery) were randomized to receive either olaparib tablets 300 mg twice a day or placebo until disease progression [118]. This led to a PFS improvement of 36 months (49.9 vs. 13.8 months) [118]. Olaparib has also been used in combination with bevacizumab irrespective of BRCA mutation with a PFS benefit [120]. Niraparib maintenance in the first line was given in those with advanced ovarian cancer after response to platinum-based therapy, irrespective of BRCA mutation status. Niraparib was given at a dose of 300 mg (200 mg for those less than 77 kg/platelet count <150,000/mm^3) once daily for 36 months or disease progression. An HRD test (homologous recombinant deficiency) was done in all patients and was defined as a score of more than 42 or presence of BRCA deleterious mutation [119]. A benefit in PFS was seen in all patients (13.8 vs. 8.2 months) though the magnitude of benefit was more in those with HRD deficiency (21.9 vs. 10.4 months) [119]. PARP inhibitors are associated with toxicity mainly myelosuppression with anemia grade III or higher seen in almost 25% of patients apart from fatigue (70%), nausea (any grade 60%), myelodysplastic syndrome (1%), and pneumonitis (2%) [118, 119]. Other PARP inhibitors like Veliparib have also shown a PFS benefit when used as maintenance in first line irrespective of BRCA status and response to platinum [121].

Presently, the overall survival data is awaited with use of maintenance PARP in first line setting. It is approved for use in first line setting. Caution, however, needs to be exercised while awaiting OS data as some rare but serious complications like AML and pneumonitis have been observed apart from other toxicities like fatigue, nausea, and myelosuppression. The sequence of PARP inhibitor use is yet to be determined and whether to use it in first line maintenance or after relapse in a platinum-sensitive setting is yet to be determined.

Maintenance Strategy -which One?

In advanced stage ovarian cancer, the question of whether to observe or use maintenance and if so which one, should probably be determined by BRCA mutation/HRD deficiency status and high-risk features. Those with BRCA mutation/HRD deficiency could be offered maintenance therapy with PARP inhibitors. Those without mutation or HRD deficiency and with stage IV disease or inoperable or sub optimally reduced stage III disease could be offered bevacizumab.

Those without BRCA mutation and high-risk features can be observed. These targeted therapies are associated with high cost and toxicity with marginal PFS benefit and the cost benefit ratio should be discussed with the patient. Observation alone is also an option even in high-risk patients or those with BRCA mutation. Observation after paclitaxel and carboplatin-based regimen is the most common strategy presently used at our institute.

Hormonal Maintenance in Low-Grade Serous Carcinomas

Low-grade serous carcinomas are not as chemo responsive as high grade (23% vs. 80%) [122]. They have a higher expression of hormone receptor (58% vs. 27%) [123]. Thus, several studies have looked at the role of hormonal therapy in low-grade cancers, though there are no randomized trials to date in view of the rarity of the tumor. In a large retrospective review of maintenance hormonal therapy in stage II-IV low-grade serous ovarian cancers, significant improvement in PFS was seen (64.9 vs. 26.4 months) [103], there was however no improvement in OS. The hormonal therapy used was mostly either aromatase inhibitor or tamoxifen [103]. Thus, hormonal maintenance therapy could be considered in stage II-IV low-grade serous ovarian cancer after completion of standard platinum-based chemotherapy.

6.3.4 Follow-up

The follow-up of ovarian cancer patients is usually once every 3–4 months for 2 years and then every 6 months for the next 3 years, then yearly or earlier at any time if symptomatic [3]. At each visit, a detailed history especially with respect to increasing dyspepsia, bloating, increasing constipation, or laxative use and clinical examination including pelvic examination needs to be done. CA 125 on follow-up visits is commonly done if baseline CA 125 is high, ultrasonography of abdomen and pelvis on follow-up may done if the CA 125 is normal at baseline or patient symptomatic. Though treating based only on rising CA125 has not been shown to improve survival [124], monitoring with CA 125 may help to understand the disease kinetics and to decide on imaging. Imaging in asymptomatic patients is not routinely indicated. If patient is symptomatic or there is a significant rise in CA125 imaging a contrast CT scan of abdomen and pelvis is usually done. It is important to note that miliary deposits in the peritoneum may not be picked up on a CT scan and should be kept in mind when assessing patients with very, high CA 125 with minimal or no abnormality on the CT scan. The decision whether to initiate treatment for recurrent disease is based on the composite of symptoms and clinical findings, extent of disease radiologically and CA125.

6.3.5 Recurrent Ovarian Cancer

Most advanced ovarian cancers will eventually recur. This relapsing remitting course with intermittent chemotherapy and progressively shorter duration of remission after each relapse makes it more like a chronic disease that is eventually fatal. The management of recurrent ovarian cancers is summarized in Table 5.

Recurrent Ovarian Cancer—To Treat or Not to Treat

The art of treating recurrent ovarian cancer is to find the right time to treat it so that it is not too early or too late. The goal is to let the patient have maximum chemotherapy-free interval without letting the disease progress to a stage which would lead to excess morbidity and mortality. The rise of CA 125 precedes clinical progression by around one and a half months on an average [125]. Thus, on follow-up, it is important to look at the patients' symptoms, clinical findings and CA125 (not only the absolute value but also the tempo of rise). If any of these are abnormal, then it is usually a trigger

Table 5 Management of recurrent ovarian cancer

Primary treatment	<6 months	6–12 months	>12 months	>24 months
	Platinum resistant	Platinum sensitive		
		Partial		
Response to platinum	X	30%	55%	75%
Platinum partner	X	– Liposomal doxorubicin – Gemcitabine – Paclitaxel	– Paclitaxel – Gemcitabine/liposomal doxorubicin	
Single-agent chemotherapy	– Liposomal Doxorubicin – Oral etoposide – Weekly paclitaxel – Gemcitabine	X	X	X
PARPi[a]	X[b]	√	√	√
Bevacizumab[a]	√	√	√	√
Palliative care	√			

[a] May be offered as maintenance—Discuss cost–benefit toxicity

[b] May be offered after > than 3 lines of therapy in patients with gBRCA mutation

to do an imaging with a contrast-enhanced CT scan of the abdomen and pelvis. If the patient is asymptomatic, the CA 125 is not extremely high (in hundreds rather than thousands), and the CT scan does not show any significant disease that is likely to cause obstruction, then the patient may be observed and followed up after 3–4 months with instructions for early follow-up if she is symptomatic. Thus, a rise of CA 125 alone should not trigger the need for chemotherapy as that has not shown to improve survival [124].

6.3.6 The Concept of Platinum Sensitivity

Platinum is the backbone of treatment of ovarian cancer and initial response to it is around 75% [104]. This is because platinum causes DNA adducts, which cannot be repaired when the cell is BRCA1 or 2 deficient or has homologous recombinant deficiency (around 50%) [45]. However, around 20% of the high-grade serous ovarian cancers have cyclin E1 overexpression (CCNE1), which is primarily responsible for resistant or refractory disease [46, 126]. Most ovarian cancers eventually relapse. The time from completion of primary platinum-based chemotherapy to disease progression is termed as the platinum-free interval [127]. Progression on treatment or within 1 month are called platinum refractory [126]. If they relapse within 6 months, they are termed platinum-resistant while beyond 6 months is platinum sensitive [126]. Those relapsing within 6–12 months are partial platinum sensitive. Of all patients receiving first-line paclitaxel and platinum, around 10% have platinum-resistant disease, 20% relapse within 6–12 months while 50% relapse between 12 and 24 months [128]. The response to re-challenge with platinum depends on the platinum-free interval. This is around 30% for those relapsing between 6 and 12 months, 55% for those relapsing between 12 and 24 months and 75% for those relapsing beyond 18 months [129]. It is important to understand that these definitions of platinum resistance and sensitivity are from an era when disease progression was diagnosed radiologically and or clinically rather than just based on serological relapse increasing CA 125 [127]. The clinical implication is that if a patient has only a serological relapse at 4 months but clinical progression after 8 months, she could still be re-challenged with a platinum-based doublet. Thus, how progression is defined needs to be specified. In patients with a platinum-sensitive relapse, use of a non-platinum agent has not shown to improve survival [130]. Hence, one of the key points in treating relapsed ovarian cancer is defining their platinum sensitivity (Table 5).

6.3.7 Platinum-Sensitive Relapse

Systemic Therapy

Chemotherapy. Patients with platinum-sensitive relapse are treated with a platinum-based doublet. This has shown to improve survival compared to single agent platinum in the ICON 4 study, where there was in improvement in response rates (54–66%), PFS from 9 to 12 months and OS from 24 to 29 months with addition of paclitaxel to platinum [131]. The platinum partner could also be gemcitabine [132] or liposomal doxorubicin [133]. Response rates and PFS are similar with use of platinum with any of the partners. However, liposomal doxorubicin compared to paclitaxel has shown an improvement PFS (11.3 vs. 9.4 months) including in the partial platinum-sensitive group (9.4 vs. 8.8 months), though the overall survival was same (33 vs. 30.7 months) [133–135]. Carboplatin hypersensitivity was less with liposomal doxorubicin (6 vs. 19%), while thrombocytopenia was less with paclitaxel (6% vs. 16%) [133]. The three platinum partners have different toxicity profiles, gemcitabine associated with hematological toxicities (grade III/IV-24%), liposomal doxorubicin with hand foot syndrome (12%) and paclitaxel with neuropathy (≥Grade II-20%) [132, 133]. Thus, patients with a platinum-sensitive relapse can be rechallenged with platinum in combination with either paclitaxel, liposomal doxorubicin, or gemcitabine.

Bevacizumab. The addition of bevacizumab to gemcitabine and carboplatin followed by bevacizumab until progression improved PFS from 8 to 12 months, though there was no difference in OS of 33 months in the updated analysis of the Oceans trial [136, 137].

PARP Inhibitors (PARPi). PARPi maintenance after response to platinum. PARP inhibitors (Olaparib, niraparib or rucaparib) may be offered as maintenance in patients with recurrent ovarian cancer who have received ≥2 prior lines of platinum-based chemotherapy (i.e., primary treatment with platinum and on relapse treated with platinum) and had a response to the last platinum therapy irrespective of the BRCA status [98, 138–140]. The treatment is continued until disease progression or toxicity [98]. They should not have received prior PARP inhibitors [98]. Three large, randomized phase III trials have been the basis for approval of PARP inhibitors in this setting (Niraparib- NOVA, Olaparib-SOLO2, Rucaparib-ARIEL 3) [138–140]. Although approved irrespective of BRCA status in this setting, the magnitude of benefit of PARP maintenance depends on whether patient has germline BRCA mutation (gBRCA mut). The median PFS in patients with gBRCA mut was 21 vs. 5.5 months, while in those with non-gBRCA mut, it was 9.3 vs. 3.9 months for PARP (niraparib) vs. placebo [138]. This should be taken into consideration when discussing regarding cost-benefit ratio of PARP. The use of maintenance PARP inhibitors has shown to improve OS (52 vs 37 months) in patients with germline BRCA mutation [141].

PARPi Monotherapy. In platinum-sensitive relapse, rechallenge with a platinum-based doublet remains the standard of care. However, in patients who have received multiple lines of platinum-based chemotherapy treating with further platinum may be difficult in view of hypersensitivity, toxicity, problems with venous access or patient's desire of oral therapy. Thus, patients with germline BRCA mutation who have platinum-sensitive relapse and have received (≥3) lines of platinum-based chemotherapy may be offered treatment with single agent PARP inhibitor (olaparib, niraparib or rucaparib) [142–144].

Secondary Cytoreduction

Secondary cytoreduction in relapsed ovarian cancer has a limited role in a select group of patients. The survival benefit of this approach is still debatable and proper patient selection is the key.

Patient selection for secondary cytoreduction was evaluated by the German/Swiss DESKTOP OVAR (the Descriptive Evaluation of perioperative Selection KriTeria for OPerability in recurrent OVARian cancer) trial group who developed AGO (Arbeitsgemeinschaft Gynakologische Onkologie) score for predicting operability in patients with recurrent disease. The parameters predictive of complete resection include a good performance status (Eastern Cooperative Oncology Group 0), no residual tumor after primary surgery or early stage at primary diagnosis (FIGO I/II) and absence of ascites in preoperative imaging (cut-off 500 mL) [61]. This score was evaluated prospectively in DESKTOP II trial and predicted 76% chances of complete cytoreduction if these criteria were fulfilled [145]. Subsequently, DESKTOP III, a phase III randomized, multicenter international trial evaluated the role of secondary cytoreductive surgery plus chemotherapy versus chemotherapy alone in platinum-sensitive recurrent ovarian cancer at first relapse with positive AGO score [146]. Most of the patients (75%) had a platinum-free interval (PFI) greater than 12 months. In the final analysis, 75% patients underwent complete resection. The median PFS was significantly greater for surgery versus not 18.4 and 14 months. The primary end point analysis also showed a significant benefit in overall survival (OS). The median OS was 53.7 months with surgery (60.7 months in those with complete resection) and 46.2 months without surgery. However, those who had incomplete resection did worse (median OS 28.8 months) compared to no surgery [146]. The other randomized trial GOG 213 trial compared the role of secondary cytoreduction followed by platinum-based combination chemotherapy with or without bevacizumab in platinum-sensitive, recurrent ovarian cancer [147]. In this trial, the median PFI was 20 months, the selection of patients for surgery was based on investigator discretion (not strictly AGO score) and 63% underwent complete resection. Around 84% received bevacizumab. In this trial, the median OS was not significantly different in the surgery (50.6 months) versus no surgery arm (64.7 months) [147]. The possible reasons for the difference in the results of the two trials could be because of the use of bevacizumab and patient selection criteria.

Thus, secondary cytoreduction may be considered in patients with platinum-sensitive recurrent ovarian cancers who have good performance status, long platinum-free interval, single site of recurrence, and no ascites who are likely to achieve complete resection.

6.3.8 Platinum Refractory and Resistant Relapse

In patients with platinum-resistant or refractory disease the goal of treatment is to achieve optimal palliation of symptoms. It is important to involve the palliative care team early even when planning for systemic therapy rather than involving them only for end-of-life care. Overall general condition of the patient needs to be assessed. The benefit in terms of survival of few added months should be weighed against toxicities, cost, repeated hospital visits, and quality of life. The patient and the family should be involved in shared decision making. Palliative care alone without further cancer-directed treatment may be considered especially in patients with poor general condition. It is important to reassure patients that they would be continued to be cared for and supported and offer hope of symptom palliation. Thus, irrespective of whether prolonging life is possible or not patients should be able to live a better, pain-free, and dignified life with their loved ones.

Systemic Therapy

Chemotherapy. Patients with platinum-resistant relapse are treated with a non-platinum agents like liposomal doxorubicin, oral etoposide, weekly paclitaxel, single-agent gemcitabine, and topotecan (which can cause significant myelosuppression) [3, 148–152]. The response rates of any of these agents are similar and varies from 10% to 15% and results in a median PFS of 3–5 months. The choice of chemotherapy would depend on previous treatments received, toxicity profile, and performance status of the patient.

Bevacizumab. In patients with platinum-resistant relapse, the addition of bevacizumab to chemotherapy (weekly paclitaxel or liposomal doxorubicin or topotecan) in the AURELIA trial improved overall response rate from 12% to 27%, median PFS from 3.4 to 6.7 months, and median OS from 13.3to 16.6 months. The risk of gastrointestinal perforation is around 2% [153]. It is thus important to carefully select patients and exclude any bowel involvement. Thus, bevacizumab is an option in these refractory patients, especially in those with rapidly filling ascites to achieve palliation.

PARP Inhibitors. Platinum resistance is a surrogate for PARP resistance and the response rate to single-agent PARP inhibitors is around 30% with a median PFS of around 5 months [154]. It is thus not recommended in platinum-resistant disease [98]. However, in patients with germline

BRCA mutations without prior PARP exposure, who have progressed after three lines of therapy, single-agent PARP inhibitor (olaparib or niraparib)is an option [143, 154].

Metronomic Chemotherapy. Metronomic scheduling of chemotherapy drugs refers to the chronic frequent administration of low-dose chemotherapy (much below their maximum tolerated dose) [155]. It has the advantage of low cost, relatively less toxicity with reasonable efficacy. It has the potential to alter tumor micro-environment in addition to achieving tumor cell kill [155]. Various drug combinations have been used in metronomic therapy. Commonly used combinations are oral cyclophosphamide, etoposide with tamoxifen, others have also used in combination with celecoxib (± pazopanib) [156, 157]. Combination of oral cyclophosphamide and pazopanib (oral angiogenesis inhibitor) also achieved meaningful PFS of 5.5 months in heavily pretreated patients [158].

Though randomized trials comparing metronomic chemotherapy to cytotoxic chemotherapy are awaited and more evidence needs to be generated, they could be an option in platinum-resistant patients where meaningful palliation may be achieved with oral therapy at low cost.

Immunotherapy

The role immunotherapy is still under investigation [99, 159, 160]. However recent data on its use in heavily pretreated patients after three to five lines of therapy showed a PFS of 2 months and an OS of 17 months (24 months in those with CPS ≥10) [99]. However, when compared to standard chemotherapy (gemcitabine or liposomal doxorubicin immunotherapy [nivolumab]), there was no benefit in PFS or OS, though in responding patients the duration of response was longer [160]. Thus, the role of immunotherapy needs to be further explored to identify whether any subsets benefit from it.

6.4 Radiotherapy

Although epithelial ovarian cancers are radiosensitive tumors, the role of radiotherapy is presently limited to the palliative setting in patients with recurrent disease. Ongoing research with newer radiotherapy techniques seeks to re-explore its role in adjuvant setting especially in clear cell carcinoma.

6.4.1 Palliative Radiation

Patients with recurrent epithelial ovarian cancers (EOC) who after standard treatments develop locoregional relapses refractory to further chemotherapy may be offered palliative radiotherapy [161, 162]. These are usually patients who have repeated pelvic recurrence without ascites. Recurrent pelvic mass with predominantly presenting symptoms of pelvic pain, vaginal mass with severe discharge and bleeding or pelvic / nodal mass causing obstructive hydronephrosis or deep vein thrombosis can be effectively palliated with radiation [162].

Also, patients presenting with painful bone metastasis or spinal cord compression, scalp or brain metastases can be offered palliative radiation to alleviate symptoms. Most common palliative radiation regimens include 20 Gy/5# or 30 Gy/10# or 6–10 Gy/1#.

6.4.2 Adjuvant/Consolidation Radiotherapy

Presently adjuvant radiotherapy is not indicated outside of a clinical trial. The success of adjuvant platinum-based chemotherapy has replaced the role of radiotherapy. This is especially so because the transperitoneal spread of ovarian cancers required whole abdomen radiotherapy (WAR), which despite potential benefit in progression-free and overall survival had significant toxicities (especially gastrointestinal) due to inadequate coverage of large target volume and poor sparing of organs at risk (OAR) due to poor technology [163, 164].

In past two decades, there have been significant advances in imaging and radiation technology (planning software and delivery) which are available for clinical use. Linear accelerator (LA) based intensity-modulated radiotherapy (IMRT), volumetric intensity modulated arc therapy (IMAT) and helical tomotherapy (HT) have shown potential to achieve uniform dose delivery to the target with significant sparing of normal tissues namely liver, kidneys and bone marrow [7, 165, 166]. There is emerging data on the use of adjuvant radiotherapy in nonserous epithelial ovarian cancer (like clear cell), especially in early-stage disease (IC, II) [7, 167]. Consideration for further research and improving outcome is warranted.

6.5 Palliative Care

Palliative care is an approach that improves quality of life of patients and their families suffering from advanced life limiting illnesses by assessing and managing the physical, psychological, social, and spiritual concerns. According to the World Health Organization, palliative care should begin at the diagnosis of such illness and continued throughout the continuum of the disease, through end of life and after the death of the patient in form of bereavement support for the family of the deceased. This has shown to have an improvement in quality of life, better patient and caregiver satisfaction with treatment and sometimes improve survival. Palliative care team comprises of doctors, nurses and social workers as core team members and psychologists, counselors, rehabilitation services, chaplains, pharmacists, dieticians, etc., as the extended team members.

Palliative care team can facilitate accurate information provision to the patient and caregivers, thus helping them clarify their preferences, concerns and goals of care. This plays a pivotal role in coordinating and facilitating the entire patient care plan, helping patients and families to make informed choices, and assisting shared decision-making process.

It is important to look after the social, practical and financial effects of cancer diagnosis and treatment on patients and their families, which is a part of comprehensive palliative care planning for them. Thus, helping them to find feasible solutions to such issues, which are often missed in medical care.

Symptoms presenting early in the course of disease may be both disease- and treatment-related. Pain and fatigue are the commonest symptoms reported throughout the illness. Other symptoms include bloating, ascites, breathlessness, nausea, vomiting, loss of appetite, indigestion, oedema, altered bowel habits, constipation, and urinary symptoms, tingling and numbness of hands and feet due to neuropathy and hair loss secondary to chemotherapy, etc. Palliative care team does a thorough assessment and evidence-based management of these symptoms, thus providing comfort to the patient. A study by Lowery et al. suggested that introducing palliative care early in course of platinum-resistant ovarian cancers, is more cost effective [168].

Malignant bowel obstruction (MBO) is one of the most common complications associated with advanced ovarian cancers. Other such conditions that may affect patients with ovarian cancers are malignant ascites, malignant pleural effusions, lymphedema, and renal failure secondary to hydronephrosis depending on the stage of illness. These symptoms can be very distressing for patient as well as the caregivers, causing effects on their physical, emotional and spiritual well-being. This leads to stress, anxiety, depression, spiritual and existential distress. These effects can cause poor tolerance to disease directed treatments and may also affect their compliance with the treatment. Palliative care referrals can help the patient and their caregivers to deal with the physical symptoms and emotional challenges faced during and post treatment, which is very vital.

6.5.1 Malignant Ascites/ Pleural Effusions

Malignant ascites can occur in almost one-third of patients with advanced ovarian cancers. Refractory ascites can cause severe discomfort, pain, anorexia, fatigue, and breathlessness in patients, impacting their quality of life. Recurrent paracentesis or indwelling peritoneal catheterization can be done for palliation of symptoms. This may lead to metabolic impairment and hypoalbuminemia. Good communication with patient and caregivers, prognostication, titrating risk vs benefit of management and clear goals of care, should be established well in advance. Similarly, thoracocentesis, indwelling pleural catheters and pleurodesis can be useful for intractable pleural effusion, along with physiotherapy.

6.5.2 Malignant Bowel Obstruction (MBO)

The tumor can cause mechanical bowel obstruction as well as ileus by peritoneal carcinomatosis, kinking the bowel loops, encasing the mesentery, and limiting the bowel motility. This can cause partial or complete bowel obstruction which can be at single or multiple sites.

Patients present with severe vomiting, obstipation, decreased appetite, or colicky abdominal pain. Examination reveals abdominal distension, tenderness and reduced or absent bowel sounds with or without ascites. Evaluation is usually with an erect radiograph of the abdomen (s/o multiple air fluid levels). A CECT of the abdomen may be needed to determine the level of obstruction.

It is important to consider the feasibility of palliative surgical management in form of diversion stoma or intestinal stenting (for single site colonic obstruction). The contraindications to surgery for malignant bowel obstruction include obstruction at multiple sites, intractable ascites, peritoneal carcinomatosis, and involvement of proximal ileum, duodenum, and stomach and previous laparotomy demonstrating diffuse metastatic disease. Palliative surgery for bowel obstruction in ovarian cancer is associated with perioperative mortality rate of 6%–32% and morbidity rate of 7%–44%, depending on type and setting of surgery [169]. The overall outcome of patient admitted with bowel obstruction is dismal with a median survival of approximately 3 months. Thus, surgery should be considered only in a select group of patients in whom meaningful palliation may be offered without significant morbidity.

Conservative measures and symptom management in the form of bowel rest by keeping the patient nil by mouth, maintaining hydration, nasogastric tube aspiration, analgesics, anti-emetics, and corticosteroids should be started immediately in all patients with MBO. The possibility of any disease-directed therapy should also be considered. If surgery or disease directed treatments are not feasible, symptom management should be continued to keep the patient comfortable and maintain good quality of life.

6.5.3 Symptom Management in MBO

In patients with refractory MBO, where the goal is palliation of symptoms only, it is important to prognosticate, look at performance status, goals of care, have ethical and shared decision-making process, limit investigations to minimal, prioritize comfort over aggressive management, consider relief of distress, and avoid futile interventions.

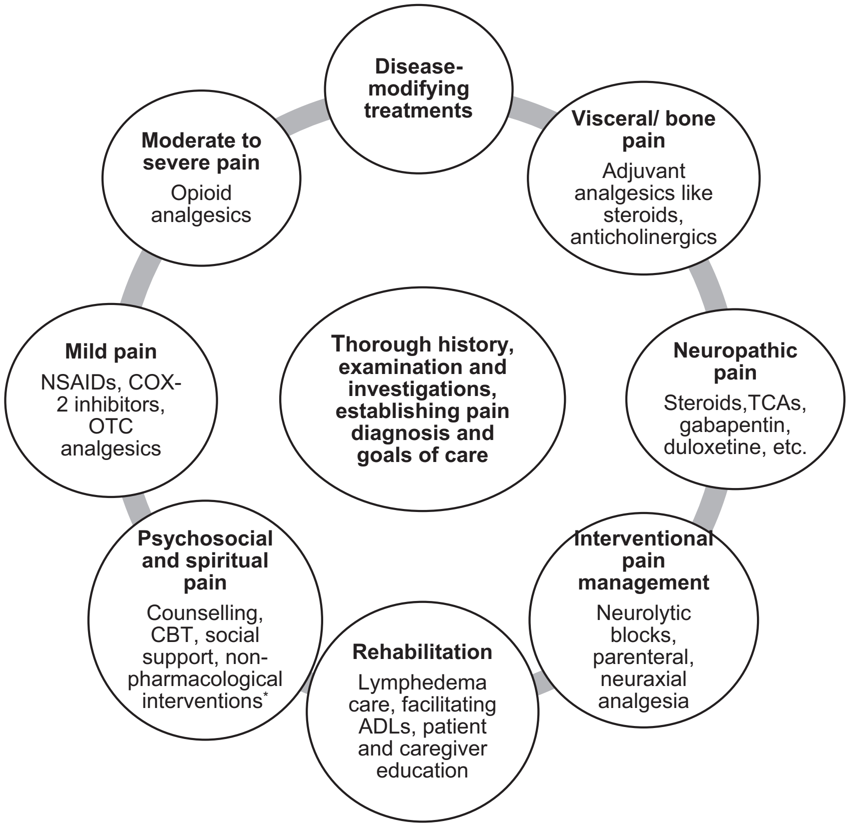
The pharmacological management of malignant bowel obstruction are detailed in Table 6 [170–177]. The optimal use of these various pharmacological measures is needed to achieve maximal palliation.

6.6 Pain

Pain in ovarian cancer patients can be caused by the primary disease, intestinal obstruction, metastases, ascites, peripheral neuropathy due to chemotherapy, lymphedema, etc. Detailed assessment including thorough history taking, assessment of "total pain," including psycho-socio-spiritual aspects, careful examination, and relevant investigations are needed to reach pain diagnosis. Pain management is guided by underlying pathological mechanisms. Multidisciplinary approach for pain management includes anticancer therapies wherever applicable, appropriate pharmacological management, psychological and rehabilitation measures, or interventional pain management in form of neurolytic blocks (Fig. 8).

Table 6 Pharmacological management of malignant bowel obstruction

Hydration	Maintain adequate hydration (1–2 L/day) by intravenous/subcutaneous route
Pain	Opioids can be considered for pain management (as per WHO analgesic ladder), route of administration can be changed to IV/SC or transdermal Hyoscine butylbromide can be added for colicky pain
Partial obstruction	Reduce bowel wall edema—steroids Stimulate gut motility—metoclopramide
Complete obstruction (if unresolvable)	Reduce intestinal secretions Treat nausea and vomiting Nil by mouth
Antiemetics [170]	Metoclopramide: 30–120 mg/24 h via s/c or IV infusion Haloperidol: 2.5–5 mg/24 h via s/c or IV infusion
Anticholinergics [171]	Hyoscine butylbromide: 40–100 mg/day/SC or IV (not to be combined with pro-kinetics like metoclopramide)
Corticosteroids [172, 173]	Dexamethasone 6–16 mg/day/IV (to be given before 2 PM, given for 3–5 days as trial) If vomiting subsides, continue oral steroids Steroids act by reducing peritumoral edema and gut wall edema. Antisecretory action by reducing salt and water secretion in the gut.
Somatostatin analogues [174–176]	Octreotide 300 mcg/day subcutaneous to reduce gut secretions
Nutrition and TPN [177]	Not recommended in MBO from advanced cancer which is irreversible May be considered in patients who are severely malnourished (BMI <18.5–22 kg/m^2 depending on age), in whom a surgery or any disease directed therapy is planned, and who cannot be given enteral feeds.



Disease-modifying treatments
Visceral/ bone pain
Adjuvant analgesics like steroids, anticholinergics
Neuropathic pain
Steroids,TCAs, gabapentin, duloxetine, etc.
Interventional pain management
Neurolytic blocks, parenteral, neuraxial analgesia
Rehabilitation
Lymphedema care, facilitating ADLs, patient and caregiver education
Psychosocial and spiritual pain
Counselling, CBT, social support, non-pharmacological interventions*
Mild pain
NSAIDs, COX-2 inhibitors, OTC analgesics
Moderate to severe pain
Opioid analgesics
Thorough history, examination and investigations, establishing pain diagnosis and goals of care

Fig. 8 Multidisciplinary management of total pain. *NSAIDs* Nonsteroidal anti-inflammatory drugs, *COX-2* Cyclooxygenase-2, *TCAs* Tricyclic antidepressants, *ADLs* Activities of daily living, *CBT* Cognitive behavior therapy

[a] Relaxation training, progressive muscle relaxation, hypnosis, distraction, guided imagery, yoga, acupuncture, music therapy, transcutaneous electrical nerve stimulation

Pharmacological management is based upon type of pain, somatic, visceral, or neuropathic and its severity. However, it is imperative to consider the patient's general condition, comorbidities, ongoing medications, compliance, response to previous treatment, history or risk for substance use disorders, or drug diversion, liver, and renal functions, understanding of symptom, caregiver support, affordability, psychological and social issues, possibility for follow up, etc. before deciding the pain management.

Thus, in patients where the goal is palliation of symptoms, it is important to limit investigations to minimal, consider relief of distress and prioritize comfort over aggressive management.

7 Conclusion

Ovarian cancers are a varied group of diseases which have perhaps little in common apart from the organ of origin. The ultimate goal of transition from a palliative to a potentially curative disease is yet to be reached for most epithelial ovarian cancers. While the endeavor to find newer treatments to improve survival continues, so must the care of the individual so that they can live longer and better.

Non-Epithelial Ovarian Cancers

Jaya Ghosh, Amita Maheshwari, Bharat Rekhi,

and Ram Abhinav Kannan

1 Germ Cell Tumor

Malignant ovarian germ cell tumors comprise (MOGCT) 3–5% of all ovarian cancers [1]. The majority of the germ cell tumors are diagnosed at a young age (median age 16–20 years, range 6–40) and in early stage (60%–70%) [2–4]. They have a favorable prognosis, the 5-year overall survival ranging from 90% to 95% in early stage tumors to 60% to 80% for even advanced cancers [3]. After fertility-sparing surgery and adjuvant chemotherapy majority, 80% retain reproductive function [5]. Thus, these are potentially curable malignancy in young girls, and every effort should be made to provide adequate treatment and ensure treatment compliance and follow-up.

1.1 Presentation

Majority of malignant ovarian germ cell tumors present at young age, usually less than 40 years [3]. Usual presentation is with abdominal pain and distension. Around one-third may present with advanced stages with ascites and pleural effusion [6]. Around 10% present with acute abdomen. It is important to take menstrual history as some present with menstrual irregularity and also to look for secondary sexual development in a young girl. Those presenting with primary amenorrhea should undergo karyotyping to rule out dysgenetic gonads [5]. Thus, in germ cell tumors as in all other cancers, a careful history and clinical examination are mandatory.

1.2 Diagnosis

Characteristically germ cell tumor markers AFP, β hCG or S LDH are raised [1]. It is important to rule out germ cell tumor in any young patient less than 40 with suspected ovarian malignancy by doing tumor markers AFP, β hCG and S LDH. Also, CA 125 may be raised because of peritoneal irritation and a mistaken diagnosis of an epithelial ovarian cancer can be made if GCT tumor markers are not done.

Germ cell tumors are usually suspected on ultrasonography and a contrast-enhanced CT scan of thorax abdomen and pelvis is done at baseline for evaluation. Usually there is a unilateral ovarian mass; however, around 10% of dysgerminomas may be bilateral [5]. In those with advanced disease, it is important to look for tumor lysis syndrome [7]. For disease limited to ovaries, biopsy is not done because it will upstage the tumor and patients are taken up for exploratory laparotomy based on tumor marker and imaging findings. In those with advanced disease, biopsy is done, especially to rule out other diagnosis like lymphoma where only LDH may be high or other metastatic adenocarcinoma (Krukenberg) which may have low levels of AFP and β hCG [8]. In patients presenting with ascites and pleural effusion, it may sometimes be difficult to distinguish between adenocarcinoma and germ cell tumors on cytology alone, and a mistaken diagnosis of an epithelial ovarian carcinoma can be made if GCT tumor markers are not done. In patients with advanced disease who are extremely sick and tumor markers are high (usually in thousands) and radiology is suggestive of ovarian malignancy, chemotherapy may be initiated without a biopsy.

1.3 Pathology

The WHO classification of germ cell tumors includes mature teratoma (dermoid) which are benign and most common and the malignant ovarian germ cell tumors which include dysgerminoma, yolk sac tumor, embryonal carcinoma, nongestational choriocarcinoma, immature teratoma and mixed germ cell tumor [1]. Apart from documenting the type of GCT, the presence of LVSI should also be noted [9]. In case of diagnostic dilemma, immunohistochemical markers may be used. Sal-like protein 4 is generally positive in all MOGCT. Dysgerminomas are positive for D240 and Alkaline phosphatase, placental type (PLAP) and OCT3/4. Yolk sac tumors are also positive for PLAP and glypican 3 [1]. Embryonal carcinomas are usually positive for Oct 3/4, CD30 and SOX2. There is an overlap of IHC markers, and thus, an IHC panel would help in diagnosis and characterization of the germ cell tumors [1, 9, 10].

1.4 Surgical Management

Given the early age of diagnosis and favorable outcome, every effort should be made to preserve fertility. The standard surgical procedure is unilateral salpingo-oophorectomy with preservation of normal adnexa and uterus with adequate staging which includes peritoneal washing, inspection, palpation and large biopsy of the omentum if normal, removal of adherent or abnormal omentum, inspection of the peritoneal surface and excision of any suspicious nodules, examination and palpation of retroperitoneal lymph nodes and sampling of firm or enlarged lymph nodes [1, 11, 12]. Random biopsies from normal looking contralateral ovary on inspection and palpation are not recommended; however, any suspicious lesion must be biopsied [1]. Suspicious lymph nodes should be removed but there is no evidence that complete pelvic and para-aortic lymphadenectomy is advantageous [1, 12]. Bilateral salpingo-oophorectomy should be done in those with dysgenetic gonads [13]. In postmenopausal patients with advanced disease or bilateral ovarian involvement, bilateral salpingo-oophorectomy and abdominal hysterectomy could be done with careful surgical staging [1]. Ovarian cystectomy alone is not recommended; however, in patients with bilateral ovarian involvement and who wish to preserve their fertility, contralateral cystectomy can be an option in selected patients [1, 5]. Fertility sparing management should be considered even in advanced disease due to chemosensitivity of tumor [1].

1.5 Chemotherapy

A landmark in the history of germ cell tumors was during 1977 when cisplatin-based chemotherapy was incorporated in the treatment of male germ cell tumors [14, 15] and which was soon incorporated to ovarian germ cell tumor [16] changing the prognosis of these tumors to highly curable malignancies. Today the standard chemotherapy regimen for GCT is bleomycin, etoposide and cisplatin (BEP) regimen [1]. This is a 5-day regimen with cisplatin and etoposide given on days 1–5 and bleomycin given on days 1, 8, and 15 every 21 days. Three to four cycles are given depending on the stage of disease [1]. One of the most important things to check before the initiating chemotherapy is the adequacy of renal function as the doses of all three drugs need to be modified based on renal function. Patients presenting with large retroperitoneal masses and obstructive uropathy may need percutaneous nephrostomy. Thus, while the BEP regimen has transformed the course of GCT from palliative to curative, the goal now is to reduce long-term toxicity while maintaining the high cure rates [12]. The Malignant Germ Cell Tumor International Consortium (MaGIC) is a collaborative effort toward that end [17].

1.5.1 Chemotherapeutic Drugs

Bleomycin

Bleomycin is an antitumor antibiotic which binds to and inhibits DNA synthesis. Less than 1% is bound to plasma proteins. It is mainly excreted by the kidneys (50%–70%) [18]. In view of low incidence of myelotoxicity [18], the dose of D8 and D15 bleomycin should not be withheld for low blood counts in the absence of any other toxicity. One of the most important and dreaded side effects of bleomycin is pulmonary toxicity (because of deficiency of bleomycin hydrolase in the pulmonary alveoli); the other common one is flagellate skin rash. Patients at high risk should be closely monitored for lung toxicity. High-risk features are age >40 years, creatine clearance <80 mL/ min, stage IV disease and cumulative dose >300 IU [18]. The incidence of significant pulmonary toxicity is around 6–10% with the 1% mortality [18, 19]. Pulmonary function tests have been done traditionally to monitor lung function. However, recently, it has been shown that though it does not correlate with subsequent toxicity and its role presently being questioned [19, 20]. What is most important is to monitor patients for cough, which has shown to correlate with toxicity [20]. Other symptoms being shortness of breath at rest or walking and chest tightness. New-onset symptoms especially cough should promptly trigger for doing an HRCT (high-resolution CT scan) of thorax [19, 20]. In case of new-onset symptoms and CT scan changes further bleomycin must be withheld. Chest infection needs to be ruled out. Pulmonary function tests and DLCO (diffusion lung capacity for carbon monoxide) may be helpful in patients with diagnostic dilemma and high-risk patients in addition to symptoms and CT scan [19]. However, bleomycin should not be withheld in asymptomatic patients without any CT chest findings only on the basis of PFT [19]. Having a symptom checklist, monitoring saturation before each dose of bleomycin and investigations based on above would be most important in avoiding bleomycin toxicity [19].

Etoposide

Etoposide is a topoisomerase II inhibitor. Its main side effect is significant myelosuppression. It is highly albumin bound and has renal clearance. It also needs dose modification in renal failure. Cumulative doses greater than 2000 mg/m^2 have been associated with acute myeloid leukemia which may develop 4–5 years after treatment [21, 22].

Cisplatin

Cisplatin acts by causing DNA adducts. Main side effects being that it is highly emetogenic and nephrotoxic. Other side effects being ototoxicity and neuropathy. Rarely, it has also been associated with thrombotic events [23]. It is important to closely monitor renal function and electrolytes during cisplatin use and use adequate hydration and antiemetics.

1.5.2 Adjuvant Chemotherapy

After surgery it is important to decide who is likely to benefit from adjuvant chemotherapy and who can be kept on active surveillance (Table 1). The FIGO (International Federation of Gynecology and Obstetrics) staging system is the same as that for nonepithelial ovarian cancer [1].

Whom Not to Give Chemotherapy—Surveillance

Patients with stage IA dysgerminoma and I A grade I immature teratoma can be kept under observation after adequate surgical staging [1]. It is important to keep them under active surveillance. Though around 80–85% stage IA dysgerminoma is cured by surgery alone, around 15% of patients relapse [1, 24, 25]. Though most of these relapses are sal-

Table 1 Adjuvant treatment of malignant ovarian germ cell tumor

Stage	Histology	Grade[a]	Management	Chemotherapy Number of cycles of BEP
Stage I				
A	Dysgerminoma		Active surveillance	
	Immature Teratoma	Grade I	Active surveillance	
		Grade II*	Consider active surveillance	
		Grade III*	Consider adjuvant chemotherapy	3
	Yolk sac tumor		Adjuvant chemotherapy preferred	3
B	Dysgerminoma*		Consider active surveillance	
	Immature teratoma*	Grade I*	Consider active surveillance	
		Grade II*	Consider active surveillance	
		Grade III*	Consider adjuvant chemotherapy	3
	Yolk sac tumor		Adjuvant chemotherapy preferred	3
C	Dysgerminoma[b]		Adjuvant chemotherapy	3
	Immature teratoma[b]*	Grade I*	Consider active surveillance	
		Grade II*	Consider adjuvant chemotherapy	3
		Grade III*	Consider adjuvant chemotherapy	3
	Yolk sac tumor		Adjuvant chemotherapy	3
Stage II	All histology		Adjuvant chemotherapy	3
Stage III	All histology		Adjuvant chemotherapy (may consider neoadjuvant chemotherapy)	3–4[c] (may omit bleomycin in cycle 4)
Stage IV	All histology		Adjuvant chemotherapy (may consider neoadjuvant chemotherapy)	4 (may omit bleomycin in cycle 4)

NOTE: *These are situations where adjuvant chemotherapy and active surveillance are both options, and the risk–benefit ratio should be discussed with the patient. When active surveillance is considered, patients must be adequately staged, postop tumor markers must be normal, and patient should be reliable for follow-up

[a] In immature teratoma, accurate grading requires adequate sampling of the entire specimen. If the entire specimen not sampled treatment as per the higher grade should be considered

[b] IC1 is a special subset of IC where both adjuvant chemotherapy and surveillance are options

[c] Adapted from [1, 6, 9]

vageable and the overall survival is close to 95%, it is important to detect these relapses early [1, 3, 26]. Immature teratoma stage IA grade I have not reported relapses in most series [27, 28].

To Give or Not to Give—Surveillance an Option

In patients with dysgerminoma stage IB adjuvant treatment is controversial though in IC adjuvant chemotherapy is usually recommended [1, 9]. However, in patients who have been adequately surgically staged active, surveillance is an option in IB and IC dysgerminoma if postoperative tumor markers are normal [1, 24]. Although around 20% to 25% of these patients may recur, they can be salvaged [24]. Thus, when planning active surveillance in these patients, it is important to ensure that they have undergone adequate surgical staging and are compliant for active surveillance and follow-up.

In Immature teratoma stage I (other than IA grade I where only surveillance indicated) the role of adjuvant chemotherapy is debatable, and it is not completely understood whether adjuvant chemotherapy reduces the risk of relapse [29]. Surveillance is an option if adequately staged, postoperative tumor markers are normal and patient is compliant for follow-up [1, 28, 29]. The most important factor predicting relapse in stage I is the Norris grade based on degree of immaturity, presence and amount of neuroepithelial component [27]. It should be noted that for accurate grading the entire tumor must be adequately sampled [27]. Those with grade I tumor (Stage IB/C) may be kept under active surveillance as the relapse rate is extremely low. Those with stage I grade II, the risk of recurrence on observation alone is around 2–20% in different series, and hence, stage IA/B may be kept under surveillance, while those with IC may consider chemotherapy [1, 27]. However, in those with grade III immature teratoma (stage I A/B/C), the risk of recurrence is to 70% with observation alone in older series [27], though in more recent series with adequate surgical staging, the relapse rate is around 20–40% [1, 24], and adjuvant chemotherapy may be considered.

Another occasionally faced problem is when a patient has high preoperative tumor marker and grade I or II immature teratoma with post op tumor markers which are normal, in this situation especially in large tumors other components may not have been adequately sampled, adjuvant chemotherapy may be considered.

Whom to Give Adjuvant Chemotherapy?

Stage I tumors with histology like yolk sac tumor, mixed germ cell tumors (other than dysgerminoma and immature teratoma which are detailed above) are treated with adjuvant chemotherapy. Though in pediatric stage I yolk sac tumor there are studies of observation alone, almost 50% of them relapse within a median time of 2 months [30] and in adults yolk sac tumors are associated with worse survival [24]; hence, adjuvant chemotherapy is the preferred option [1]. Stages II, III and IV of all histology are treated with adjuvant chemotherapy [1, 9].

How Many Cycles of Chemotherapy?

For early stage disease (stage I where chemotherapy indicated and stage II), usually three cycles of BEP are given. In patients above 40 years of age, bleomycin should be avoided, and four cycles of EP may be used instead. There is an increasing attempt in stage I tumors to reduce the number of chemotherapy cycles from three to two [9], though more data in adults is awaited.

In patients with advanced stage disease stage III, three cycles of BEP in case of completely resected disease and four cycles in patients with macroscopic residual disease [31], while in patients stage IV disease four cycles of BEP is given. In patients receiving four cycles, bleomycin may be omitted in the fourth cycle to avoid pulmonary toxicity [1, 9]. In patients with advanced disease in whom bleomycin cannot be given, other chemotherapy options are ifosfamide, etoposide and cisplatin [9].

1.5.3 Neoadjuvant Chemotherapy

In patients with advanced stage with extensive intra-abdominal disease, poor performance status where upfront surgery is likely to result in increased morbidity or fertility sparing surgery may not be possible, neoadjuvant chemotherapy (NACT) followed by fertility sparing surgery can be undertaken [6, 32]. In view of high chemo-sensitivity of these tumors, extensive surgical procedures should be avoided [9]. A response assessment is usually done after 2 cycles with tumor markers and CT scan. NACT with 4 cycles of BEP resulted in 70% patients achieving a complete and 22% partial response, who were then able to undergo fertility sparing surgery [6]. The estimated 10-year disease-free survival with NACT was 87% [6]. In patients who are extremely sick, low-dose induction chemotherapy (3 days of Cisplatin 20 mg/m^2 and Etoposide 100 mg/m^2) instead of the routine 5 days, and regular BEP postponed to D15) may be used taking cue from male GCT [33]. In these patients it is important to monitor for tumor lysis syndrome. Thus, in patients with advanced disease and poor performance status, NACT is a valid treatment option.

1.6 Follow-Up

Most guidelines recommend two monthly follow-ups (monthly for those on active surveillance) with clinical examination and tumor markers and ultrasound abdomen and pelvis for the first 6 months and then 2–3 monthly in second and third year, 6 monthly in fourth and fifth year and then yearly; a chest X-ray 6 monthly is also recommended for 2 years [1, 9]. For those on active surveillance, a 6 monthly CT scan in the first year at least, and some recommend for 2 years [1, 9]. Patients should be carefully counseled to avoid pregnancy in the first 2 years post treatment because it enhances the maximum chance of recurrence [34].

However, as such an intensive follow-up is not routinely feasible, at our institute, we usually follow patients three monthly in the first 2 years and then 6 monthly until 5 years, with clinical examination, tumor markers and ultrasonography of abdomen and pelvis. A CECT scan of thorax, abdomen and pelvis is done if tumor markers are rising or abnormal findings on ultrasound or symptoms. On follow-up, it is common to find functional ovarian cysts in the opposite ovary, and it is important to be aware of them, especially if tumor markers are normal. These are usually simple cysts that disappear post menstruation. Thus, a short follow-up after month post menstruation resolves the diagnostic dilemma and avoids further investigation. Occasionally on follow-up when patients present with rising β hCG, it is important to rule out pregnancy. The involvement of the family and medical social workers is important to ensure a regular follow-up.

1.7 Reproductive Outcomes

After fertility-sparing surgery and adjuvant cisplatin-based chemotherapy, 80–90% of patients resume menstruation within a median time of 6 months post treatment completion and most within a year [35–37]. Premature ovarian failure is seen in only around 3% of patients [38]. The infertility rate is higher in those receiving four cycles of BEP (33%) compared to three cycles (17%) [36]. Among those desiring conception, 80–90% have successful fertility outcomes [35–38]. The obstetric complications and miscarriage were not different from general population [37–39]. MOGCT have favorable fertility outcomes and patients should be reassured regarding the same prior to starting treatment.

1.8 Recurrent Disease Management

There is no definite treatment strategy for recurrent MOGCT. It depends on patients' previous lines of therapy and mainly extrapolated from male germ cell tumors [9]. If they have relapsed after 4–6 weeks of treatment completion, they can be rechallenged with platinum-based protocol like TIP (paclitaxel, ifosfamide, cisplatin) or VbIP (vinblastine, ifosfamide cisplatin), etoposide, ifosfamide and cisplatin (VIP) [40–43]. Treatment options for those relapsing on treatment or within a month include gemcitabine and paclitaxel with or without oxaliplatin [31]. If on recurrence tumor markers are normal, then it is likely to be a growing teratoma in which case surgery would the treatment of choice [9]. The role of autologous stem cell transplant and the results of the TIGER study which is a randomized phase III trial comparing conventional-dose chemotherapy using paclitaxel, ifosfamide and cisplatin (TIP) with high-dose chemotherapy using mobilizing paclitaxel plus ifosfamide followed by high-dose carboplatin and etoposide (TI-CE) as first salvage treatment in relapsed or refractory germ cell tumors, are awaited in male germ cell tumors [44].

1.9 Late Effects of Treatment

As many patients with MOGCT will be long-term survivors, it is important to monitor for late effects. Most of the data is from long-term follow-up of testicular cancers [45, 46]. Late effects like hypertension, hypercholesterolemia, ischemic heart disease, metabolic syndrome, renal dysfunction and ototoxicity need to be monitored [45, 46]. Pulmonary toxicity can be caused primarily by bleomycin but also by cisplatin [45]. The risk of second malignancies though low (standardized incidence ratio 1.4–1.8 needs to be monitored) [45].

1.10 Survivorship—Cure and Care

As with childhood cancer survivors' adolescents and young adults after being cured of their cancer need to be monitored systematically and cared for late effects of treatment as well as educational and socio-economic rehabilitation [47, 48]. The ultimate goal being that after being cured of their cancer, they become "resilient and autonomous" individuals with "optimal health-related quality of life" and "accepted in society at the same level" as their peers [47, 48].

2 Sex Cord Stromal Tumors

Sex cord tumors are a heterogeneous group of neoplasms which comprise 3–5% of all ovarian malignancies [1, 9]. Many of them have endocrine manifestations. They occur over a wide range of age groups, though many occur in middle age and in postmenopausal age groups [1]. They generally present in early stages (60–90%) and are usually unilateral [1, 9]. Surgery forms the mainstay of treatment in early stages. The 5-year overall survival rates are 75–95% in stage I tumors, 55–75% in stage II and 22–55% in stage III and IV [1, 49]. They may have late recurrences [50]. Thus, stage and histological subtype and features are the most important prognostic markers for these rare ovarian tumors.

2.1 Pathology

Ovarian sex cord stromal tumors with malignant potential mainly comprise of granulosa cell tumors and Sertoli and Leydig cell tumors. The granulosa cell tumor can be juvenile or of the adult type. These are two distinct histological subtypes. They are associated with hyperestrogenic states [1, 49]. The histological characteristic of adult granulosa cell tumors is the presence of Call Exner bodies (rosette like structures with eosinophilic material). In case of diagnostic dilemma, a panel immunohistochemical markers like inhibin, calretinin and FOXl2 may be used [1, 49]. Somatic mutations in the FOXL2 found in adult granulosa cell tumors are its potential drivers [51].

Sertoli-Leydig cell tumors usually are associated with androgen secretion and clinical virilization in 70–85% of these patients [49]. Pathological evaluation includes grade, histological features like retiform pattern and the presence of heterologous elements (mucinous, glandular, skeletal muscle or cartilage), which confer a worse prognosis [9]. DICER 1 mutations which cause disruption in the biogenesis and disruption of micro RNA expression of several genes have been associated with several rare cancers including Sertoli-Leydig cell tumors especially moderate and poorly differentiated ones [9, 52, 53].

2.2 Prognostic Factors

Age younger than 40 years, tumor size greater than 10 cm, mitotic index 5 or more /10 high power field are associated with poor prognosis though the data on the same is conflicting [49].These features do not constitute an indication for adjuvant chemotherapy in the absence of other risk factors. Surgical staging appears to be an independent prognostic marker [54]. The FIGO staging system is the same as that for epithelial ovarian cancer [1]. Preoperative tumor rupture was the most significant risk factor for relapse [49, 55].

2.3 Presentation

Clinically, they present with abdominal pain, distension and sometimes with risk of torsion. Granulosa cell tumors, juvenile subtype is more common in the adolescents and young adults while the adult type is more common in the peri- and postmenopausal age groups [49]. They present with abnormal vaginal bleeding. Sertoli Leydig cell tumors occur in second and third decades and 70–85% have hirsutism and clinical virilization [1, 49]. A detailed family history of other neoplasms should also be taken in patients with Sertoli-Leydig cell tumors and genetic counseling may be considered.

2.4 Diagnosis

Usually, an ultrasonography is done at baseline. Evaluation includes a contrast CT scan of abdomen and pelvis or an MRI. The radiological appearances are heterogeneous. The granulosa cell tumors are characterized by multicystic masses with solid components. On MRI, the tumors have sponge-like appearance [56].

Tumor markers Inhibin B is raised in granulosa cell tumor though CA 125 may also be nonspecifically raised [57]. It is important to know that there may be variation of S Inhibin B in the menstrual cycle with lowest level in late luteal phase [58]. Hormonal levels of estrogen, dehydroepiandrosterone, testosterone, luteinizing hormone and follicle stimulating may be done depending on the signs and symptoms of excess hormone production [9]. Other tumor markers like AFP, β hCG and LDH may also be done to rule out germ cell tumors in young patients.

In adult patients with granulosa cell tumor in endometrial sampling is recommended as because of the hyper estrogenic state there is an association with endometrial cancer in 3–6% patients [57].

2.5 Surgery

The extent of surgery in patients with SCST depends on age, histological subtype and desire for fertility preservation. In young patients desirous of fertility with macroscopically in stage IA disease a fertility-sparing surgery with unilateral salpingo-oophorectomy and adequate surgical staging is considered safe. However, patients with greater than stage I disease and postmenopausal women undergo total abdominal hysterectomy with bilateral salpingo-oophorectomy and complete surgical staging. Complete surgical staging includes peritoneal cytology, inspection of peritoneal cavity and biopsy of any abnormal areas and infracolic omentectomy. Systematic lymph node dissection is not indicated unless they are suspicious [1, 9].

2.6 Role of Adjuvant Chemotherapy

2.6.1 Stage IA/B

Granulosa Cell Tumor (Adult or Juvenile)

May be followed up after surgery alone as the 5-year survival after surgery alone is close to 95%. Hence, adjuvant chemotherapy is not indicated [1, 50].

Sex Cord Stromal Tumors

In those with heterologous or poorly differentiated elements, adjuvant chemotherapy is indicated while others without these poor risk factors may be followed up after surgery [1, 9].

2.6.2 Stage IC

Granulosa Cell Tumor

Juvenile granulosa cell tumor adjuvant chemotherapy in stage IC is indicated, although in IC 1 active surveillance is an option [1].

Adult Granulosa Cell Tumor

Those with stage IC1 may be followed up after surgery [1, 54, 55]. Patients with stages IC2 and IC3 receive adjuvant chemotherapy especially if they also have high mitotic index [1, 49]. Active surveillance is an option in IC2 and C3 [1].

Sex Cord Stromal Tumors

Adjuvant chemotherapy is indicated in all stage IC [1, 9].

2.6.3 Stages II–IV

All patients should receive chemotherapy irrespective of histology [1]. In patients with stage IV disease chemotherapy would be given with palliative intent.

2.6.4 Chemotherapy

Three to four cycles of BEP is the standard treatment with bleomycin omitted in those above 40 years of age. Paclitaxel and carboplatin is another active combination, which is given for six cycles and can be used in adjuvant setting. GOG 264 trial is comparing the efficacy of both and results are awaited [1, 9].

2.7 Recurrent Disease

In patients with granulosa cell tumors especially those with late recurrences, re-surgery with maximum cytoreduction where feasible is indicated [1, 9, 55]. The chemotherapy regimens used in recurrent settings include paclitaxel/carboplatin, doxorubicin, paclitaxel, ifosfamide based regimens [1, 9, 49]. The recent randomized phase II trial has shown the benefit of weekly paclitaxel with a 6-month PFS of 70% and no additional benefit of bevacizumab [59]. Hormone therapy in recurrent settings includes aromatase inhibitors, leuprolide and tamoxifen. Hormone therapy like Megestrol and GNRH agonists can also be used in relapsing patients [1, 49]. The phase II PARAGON study evaluating the role of aromatase inhibitors in the metastatic setting has shown a clinical benefit rate of 80% at 3 months and a median PFS of 8.6 months [60].

2.8 Follow-Up

These tumors may recur late even up to 20 years later and thus the need for life-long follow-up [54]. Patients are usually followed up with clinical examination, ultrasonography and tumor markers where indicated every 3–4 monthly in the first 2 years and then 6 monthly in years 3–5 and then yearly. CT scan is done based on clinical indication [9].

3 Small Cell Carcinoma Ovary of the Hypercalcemic Type

This is a rare yet aggressive tumor with poor prognosis and as the name suggests is associated with hypercalcemia. Thus, the work-up for these patients in addition to a CT scan of abdomen and pelvis, CA 125, includes measurement of serum calcium and chromogranin A. Pathologically, the differential diagnosis is of small round cell tumor and immunohistochemistry for SMARCA4 if available may be useful as these are associated with loss of nuclear immunoreactivity [9].

In view of the aggressive nature of the tumor, surgery comprises of total abdominal hysterectomy and bilateral salpingo-oophorectomy with peritoneal staging and full pelvic and para-aortic lymphadenectomy even in early stage. In advanced stages, surgery may be done upfront or debulking surgery after three cycles of chemotherapy if complete removal of the peritoneal disease can be achieved. The chemotherapy regimen used is cisplatin and etoposide and six cycles are given [9].

Despite all treatment outcome for these tumors is poor and newer treatment avenues need to be explored.

4 Conclusion

Nonepithelial ovarian cancers are a diverse group of diseases. The transition from a palliative to a potentially curative cancer was achieved for germ cell tumors almost 50 years back, and that inflection point is yet to be reached for the other ovarian cancers. The endeavor thus is to improve survival while reducing late effects of cancer treatment.

1 Epidemiology and Pathogenesis

Being rare, bone sarcomas present unique challenges both in diagnosis and treatment. Osteosarcoma, Ewing's sarcoma and chondrosarcoma are the three most frequent primary bone sarcomas [1, 2].

Osteosarcoma is the most common primary bone cancer in children and adolescents. The incidence has two peaks, with an age-adjusted incidence of 4 per million in patients ≤25 years or ≥59 years of age, and ≤2 per million among those aged 25–59 years. The incidence of osteosarcoma peaks with onset of puberty, in boys reported at ages 15–19 years and in girls at ages 10–14 years [1, 3]. In a series of 853 patients from Tata Memorial Hospital, Mumbai, the mean age was 19 years (range 3–64 years) [4]. The pathogenesis includes a combination of genetic changes including abnormalities in RB gene and P53 genes. The most common syndromes associated are Rothmund–Thomson syndrome, Li–Fraumeni syndrome and Werner syndrome. The second incidence peak in the elderly (age ≥60 years) is associated with Paget's disease or postradiation sarcomas [5].

Ewing's sarcoma, another bone sarcoma seen in children and adolescents, is discussed in a separate chapter in this book.

Chondrosarcomas are rare, representing approximately 20% of primary musculoskeletal malignancies. Most patients are in the fifth decade or older. Patients with secondary chondrosarcomas from Ollier's disease or Maffucci's syndrome present earlier, usually in the third or fourth decade.

2 Diagnosis

Patients with bone sarcoma present with swelling or pain that may disturb sleep at night and occasionally results in a pathological fracture. Complete clinical diagnosis involves establishing histological diagnosis, mapping disease extent and assessing various treatment options. This includes a thorough history and physical examination, details of prior intervention and treatment, clinical examination, assessment of the involved region, regional lymph nodes (an uncommon site of metastases) and lungs (commonest site for metastases). This necessitates local imaging, biopsy and imaging for systemic staging.

2.1 Radiological Imaging of the Involved Bone

Plain radiographs in two planes (anteroposterior and lateral) covering the whole extent of the involved bone are advised as an initial evaluation. In addition, an MRI and in occasional cases a CT scan is recommended. The additional imaging helps demonstrate extent of disease, relationship to neurovascular structures and adjacent joints, delineate necrotic versus viable solid tumor that helps guide biopsy, evaluates for skip lesions (separate tumor nodules within the same bone) and helps estimate surgical margins and create a tentative plan for eventual surgical resection. Imaging is repeated presurgery (toward the end of neoadjuvant therapy) to assess therapeutic response, reconfirm surgical margins (which are planned based on imaging showing the maximum extent of disease) and evaluate reconstructive options.

2.2 Biopsy

Biopsy is performed after completion of all local imaging. Placement of the biopsy site is critical as it can significantly impact limb salvage and reconstructive options [6]. Due diligence is needed to place it appropriately so as to take the shortest, safest route to source adequate viable tissue. It is best that biopsies be planned by the treating team or after an orthopedic oncology consult. A core needle biopsy is sufficient and standard of care in most cases. An open biopsy is required in a few cases after failure of yield or diagnosis after multiple well-targeted needle biopsies or if additional tissue is required for research or tumor repositories (after appropriate consent). For challenging anatomic locations or where a large component of the tumor is necrotic, image guidance (IITV imaging/CT scans/ultrasound) may be used to increase tumor yield [7, 8]. As a general rule, biopsies are performed away from sites of pathological fracture. Due care is necessary to avoid contamination of the adjacent joint, critical structures or multiple compartments. Often special cytogenetic or molecular oncology testing may be necessary to arrive at a diagnosis. Microbial cultures are sent when infection is suspected or is a differential diagnosis. Frozen section may be used to ascertain viability of tissue sent in cases with predominantly necrotic tumor [9]. Biopsy cores should be processed together. The material must not be divided with the intent of sending it to different laboratories. Due to the heterogeneous nature of sarcomas, separating tissue or cores lead to improper reports and avoidable confusion. Discrepancy is sorted by seeking second/subsequent opinions on the same material by sending slides and blocks for review. Fine-needle aspiration cytology is discouraged for diagnosing bone neoplasms as the rate of nondiagnostic or nonrepresentative sampling is high due to absence of matrix in the sample (FNAC yields cells not matrix). If an open biopsy is needed, meticulous hemostasis, use of drains and precautions to avoid a pathological fracture through the bony window viz., a small oval window, cement plugging, avoiding sharp corners etc. must be taken. Confirmation of diagnosis helps guide appropriate staging, the need for molecular genetic testing, baseline organ assessment and supportive care including fertility preservation in preparation for neoadjuvant therapy. A biopsy plays a vital role in diagnosis and has a bearing on definitive management and disease-specific-survival of the patient. It requires considerable thought and planning prior to its execution and adequate correlation of the clinical evaluation, imaging and histopathology in order to be of maximum benefit to the surgeon and the patient.

2.3 Staging

Staging is guided by the final histologic diagnosis toward evaluating the commonest metastatic sites. It helps map disease burden, communicate prognosis and decide intent of treatment. Multidisciplinary input is often required to plan the treatment course and consider options for clinical trial recruitment. Lungs are the commonest site for metastases in all bone sarcomas. A noncontrast thin section (1 mm or less) scan using high resolution helical CT is most sensitive and detects even small nodules [10]. Technetium radionuclide bone scanning is the recommended method to evaluate for osseous metastases and skip lesions [11]. A fluorodeoxyglucose (FDG)-positron emission tomography (PET) scan though not the standard of care may be used and may add value in response assessment to neoadjuvant therapy and prognostication. The commonest staging systems used were developed by Enneking et al. and The American Joint Committee on Cancer (AJCC). The Enneking system characterizes tumors that have not metastasized based on their histological grade (low grade 1 vs. high grade 2). These are subdivided into A for tumors that are intramedullary and B for tumors that extend beyond the cortex. Stage 3 are tumors that have metastasized [12]. Though the AJCC classification has not been adopted widely by the sarcoma community, the updated 17th edition of AJCC has distinct groups for axial, appendicular skeleton, pelvis, facial bones and the skull [13]. While beneficial in comparing outcomes across institutes for different stages, it adds little value in individual patient prognostication and does not consider treatment variables that alter survival (response to chemotherapy, for instance).

3 Osteosarcoma

Osteosarcoma is defined as a primary malignant tumor in which the malignant mesenchymal cells produce osteoid and/or immature bone. There are often areas with chondroblastic or fibroblastic differentiation. Hematoxylin and eosin-stained specimens remain the gold standard for the histological diagnosis, but recently molecular signatures have assisted in diagnosing certain bone tumors (Table 1).

The World Health Organization classification of osteosarcoma includes: conventional, telangiectatic, small cell, low-grade central, secondary, parosteal, periosteal and high-grade surface variants [14].

3.1 Conventional High-Grade Osteosarcoma

It commonly occurs in the metaphyseal region around the knee, but may occur in any bone. It presents as a mixed lytic-sclerotic destructive lesion with a wide zone of transition and an aggressive periosteal reaction often with a sunburst pattern and presence of a Codman's triangle (Fig. 1). Vast majority of osteosarcomas show fluffy, amorphous cloudlike opacities within the lesion that characterize osteoid

Table 1 Molecular signatures and their clinical applications in osteosarcomas and chondrosarcomas

Tumor	Molecular abnormality	Differential diagnosis	Test method
Low-grade central osteosarcoma	Ring chromosomes with CDK4 and MDM2 amplification	Fibrous dysplasia, desmoplastic fibroma, fibrosarcoma	FISH, IHC, quantitative PCR
Parosteal osteosarcoma	Ring chromosomes with CDK4 and MDM2 amplification	Myositis ossificans, osteochondroma, bizarre parosteal osteochondromatous proliferation, fibrous dysplasia	FISH, IHC, quantitative PCR
Chondrosarcoma (CS)	Somatic IDH1 and IDH2 mutations present in 30%–90% of sporadic tumors. Mosaicism of post meiotic mutations in Maffucci's and Ollier's disease is seen in ~100%	Chondroblastic osteosarcoma, mesenchymal CS, chordoma (with soft tissue extension), periosteal/parosteal osteosarcoma	PCR-based methods
Dedifferentiated chondrosarcoma (CS)	Somatic IDH1 and IDH2 mutations originating from low-grade CS	Chondroblastic osteosarcoma, undifferentiated high-grade bone sarcoma, dedifferentiated chordoma	PCR-based methods
Mesenchymal chondrosarcoma (CS)	Rearrangement leading to HEY1-NCOA2 fusion transcripts	Chondroblastic osteosarcoma, dedifferentiated CS, Ewing's sarcoma	RT-PCR, FISH

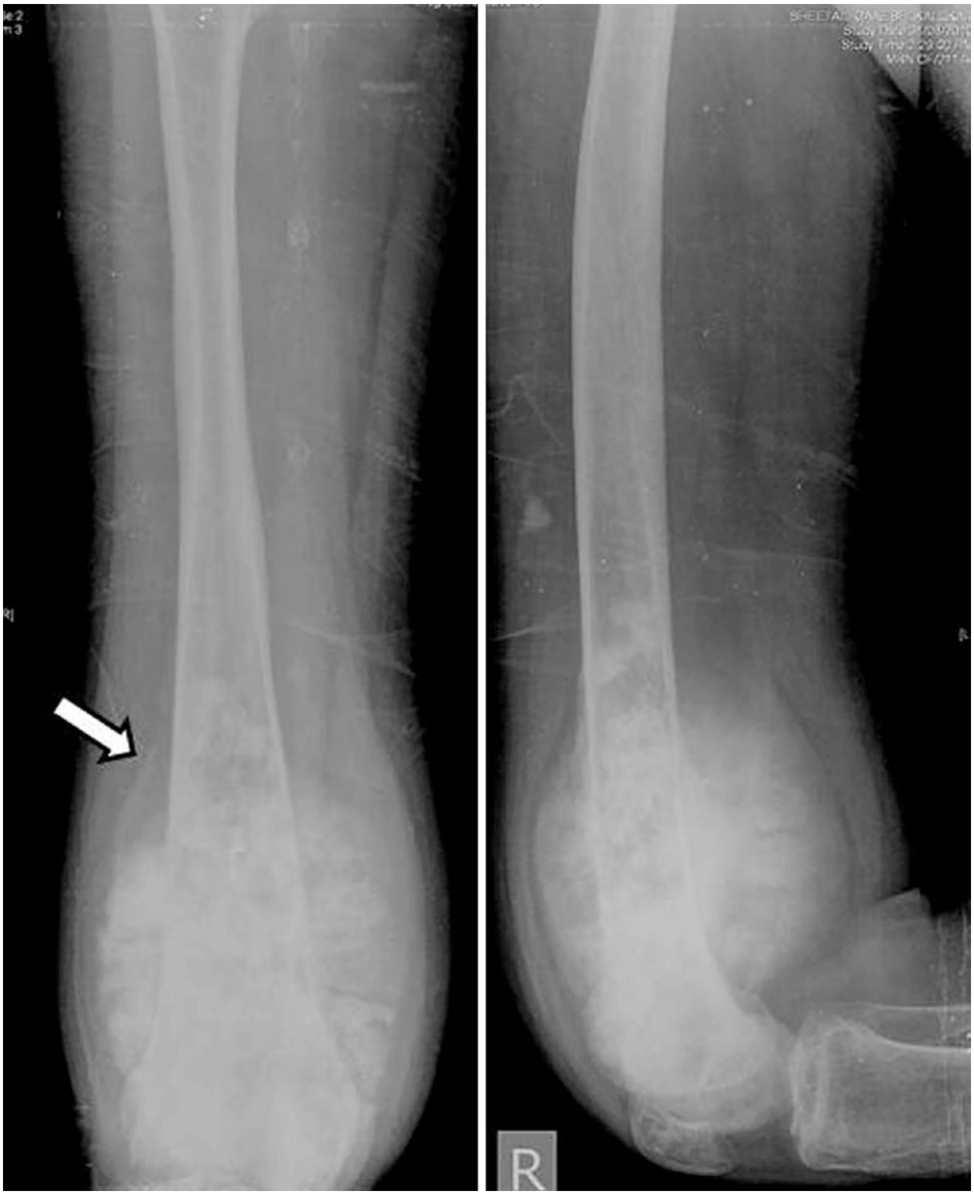

Fig. 1 Osteosarcoma. Radiograph of a high-grade conventional osteosarcoma of the distal femur showing a periosteal reaction with a Codman's triangle (arrow)

matrix alongside a large unmineralized soft tissue component [15].

3.2 Parosteal Osteosarcoma

It accounts for around 5% of osteosarcomas. It is commonly metaphyseal in location with the distal posterior femur being the most frequent site. It appears as a lobulated, exophytic mass, with dense ossification and a “stuck on” appearance adjacent to the cortex. A string sign which is a plane between tumor and adjacent normal cortex may be present in radiographs. Invasion into the medullary canal may occasionally be observed. It is predominantly low signal on both T1 and T2 MRI images (Fig. 2). Differential diagnoses include benign and malignant entities such as osteochondroma, myositis ossificans, periosteal chondroma, periosteal chondrosarcoma and other juxtacortical osteosarcomas [16].

3.3 Periosteal Osteosarcoma

This is the second most common juxtacortical osteosarcoma. It is usually seen in diaphyseal long bones. It is predominantly cartilaginous and is an intermediate- or high-grade tumor. It presents with a soft tissue mass and an irregular periosteal reaction associated with cortical thickening. Intramedullary invasion is documented but rare (Fig. 3). On MRI it has T2 hyperintense areas with small foci of T1 hypointense areas with calcified matrix. It is difficult to distinguish it from a high-grade surface osteosarcoma, the latter is more likely to include the whole circumference and invade the medulla.

3.4 High-Grade Surface Osteosarcoma

This is a rare variant and occurs in the same location as periosteal osteosarcoma with the femur being the commonest site. Imaging shows dense ossification, periosteal reaction and cortical erosion. Often circumferential thickening is seen and the rate of intramedullary invasion is commoner than in periosteal osteosarcoma. Differential diagnosis is similar to periosteal osteosarcoma.

3.5 Telangiectatic Osteosarcoma

This is an aggressive form of osteosarcoma, commonly occurring at metaphyseal sites in long bones, usually in the first two decades of life. It characteristically causes aggressive cortical destruction, expansion, a large soft tissue component and minimal sclerosis. MRI images show multiple fluid levels with hemorrhagic cystic components. Subtle osteoid may be visible on CT images. Enhancing nodular thick septa with presence of osteoid mineralization differentiate it from an aneurysmal bone cyst on MRI.

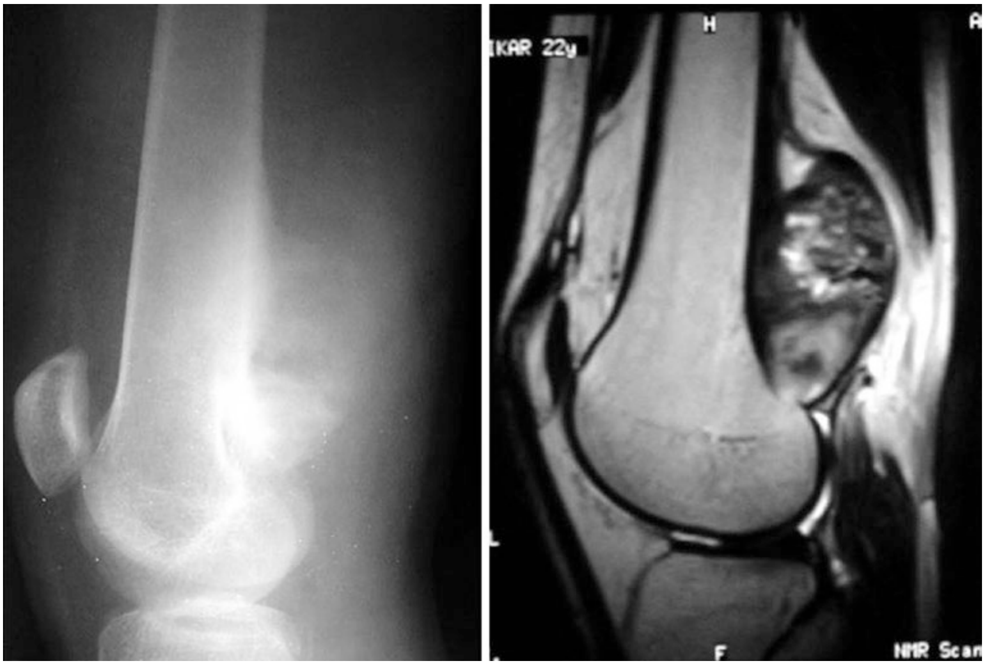

Fig. 2 Parosteal osteosarcoma. Radiograph and MR images depict a parosteal osteosarcoma of the posterior distal femur

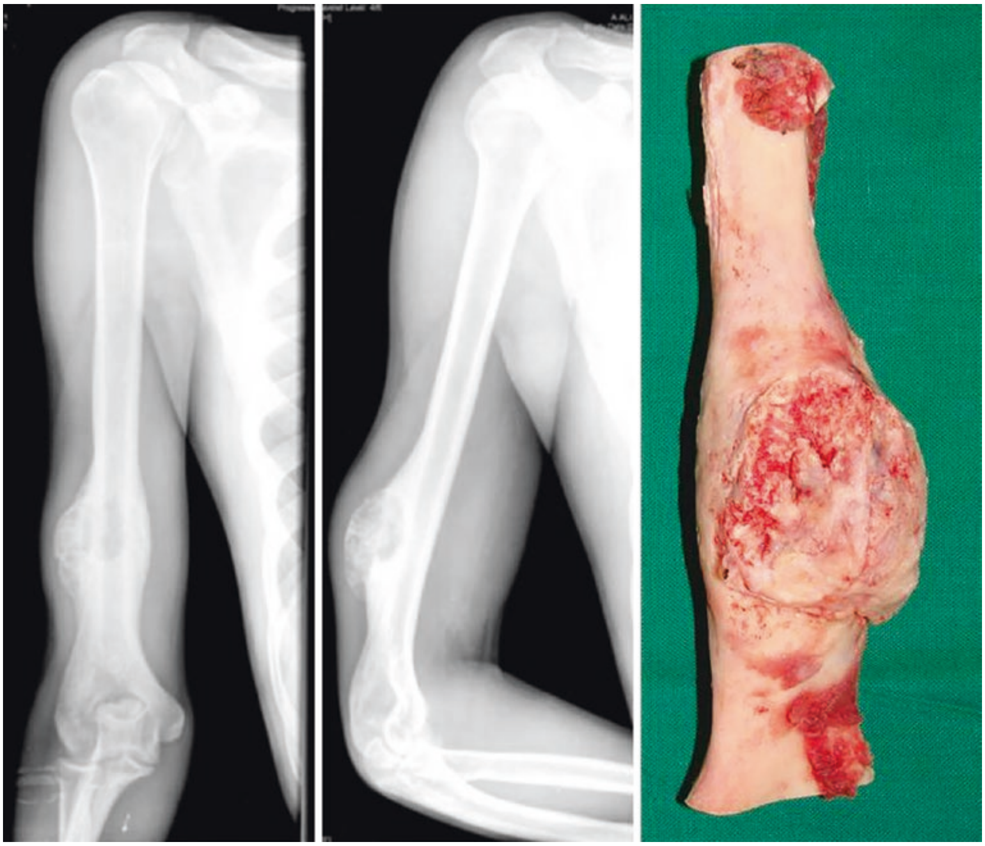

Fig. 3 Periosteal osteosarcoma. Radiograph of a periosteal osteosarcoma of the humerus with the histology specimen demonstrating a surface tumor

3.6 Small Cell Osteosarcoma

This is a rare variant of osteosarcoma. While morphology may mimic Ewing's sarcoma, presence of osteoid matrix and absence of EWS-ETS translocation help distinguish it from Ewing's sarcoma. Imaging features show permeation, lysis and cortical destruction often accompanied by a large soft tissue component. A differential diagnosis is lymphoma of bone which may also show permeative lysis with large soft tissue component but calcification is uncommon.

3.7 Low-Grade Central Osteosarcoma

This uncommon subtype of osteosarcoma occurs in the intramedullary location of femur or tibia. It has much better prognosis than conventional osteosarcoma and surgical resection is adequate. The radiograph shows an expansile lytic lesion with thick trabeculae or occasionally a dense sclerotic pattern. It commonly is associated with cortical disruption and soft tissue expansion. Benign fibro-osseous lesions which include fibrous dysplasia, nonossifying fibroma and desmoplastic fibroma are common radiological differentials.

4 Chondrosarcoma

Chondrosarcoma is a malignant tumor producing cartilaginous matrix and the primary variant is the third most common primary malignant tumor arising in bone. The subtypes include primary, secondary to osteochondroma, clear cell, juxtacortical, mesenchymal, dedifferentiated and extra skeletal.

On histopathology there is an increased variation in cell size and often bi nucleated cells. Mitotic figures are rare. Myxoid and cystic areas indicate malignancy. Lobular nests of cartilage with varying degrees of cellular atypia are common. As cellular atypia increases, the grade of the malignancy increases: Grade 1 chondrosarcoma is moderately cellular (vis-à-vis enchondroma) and shows mild nuclear atypia and bi-nucleation. Grade 2 chondrosarcoma is more cellular and shows more nuclear atypia. Grade 3 chondrosarcoma is very cellular and shows pleomorphic and anaplastic tumor cells which are mitotically active. Necrosis may be seen. Immunohistochemistry is positive for vimentin and protein S-100, but negative for cytokeratin and EMA.

4.1 Conventional Intramedullary Chondrosarcoma

It presents in the long tubular bones and flat bones, femur being the most common site. The innominate bone is affected in up to one fourth of the cases. Radiographs show a mixed lytic sclerotic pattern of mineralization, typical ring and arc chondroid matrix, deep endosteal scalloping (over two-thirds the bone thickness) and soft tissue extension (Fig. 4). The high water content leads to high T2 signal on MRI and low attenuation on CT images. Distinction of grade 1 chondrosarcoma and enchondroma is challenging on pathology alone. Imaging and clinical details are essential in attributing the correct grade for optimal therapy. FDG PET CT scan is currently being evaluated to help distinguish various grades of chondrosarcoma. Presence of a soft tissue extension precludes the diagnosis of a benign enchondroma. Enchondromas of the hand and feet may cause significant radiological endosteal scalloping while remaining benign [17].

4.2 Clear Cell Chondrosarcoma

This is a rare and slow growing variant affecting long tubular bones, most commonly the epimetaphyseal region of the femur and humerus. Radiographs show a predominantly lytic lesion, cartilaginous matrix is not as frequent. T2 weighted MRI images are heterogeneous with high signal intensity.

4.3 Juxtacortical Chondrosarcoma

These are also referred to as periosteal or parosteal chondrosarcoma. Radiographs show a dense mineralized lesion with erosions in the underlying cortex. Periosteal osteosarcoma is a close differential diagnosis due to its predominant cartilaginous matrix. The latter present in a younger population (10–25 years), are commonly diaphyseal and are associated with a hair on end periosteal reaction helping to distinguish it from juxtacortical chondrosarcoma.

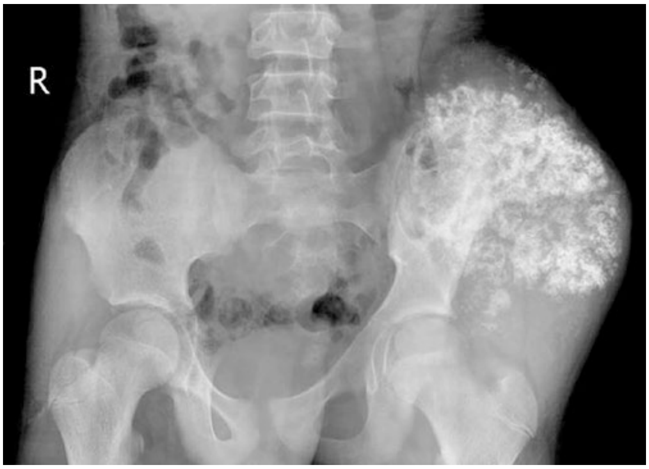

Fig. 4 Chondrosarcoma. Radiograph of a chondrosarcoma of the pelvis, a common site for a chondrosarcoma

4.4 Mesenchymal Chondrosarcoma

This is an aggressive variant with more propensity to metastasize. The axial skeleton is more commonly affected than the appendicular skeleton. Radiographs show destructive lesions with cortical permeation and soft tissue component. Cartilaginous matrix enhancement is heterogeneous and often lacks peripheral enhancement. Pathology often shows round cells similar to that seen in Ewing's sarcoma intermixed with a mesenchymal component.

4.5 Dedifferentiated Chondrosarcoma

This is a highly aggressive variant with very poor 5-year survival rates. Femur, pelvis and scapula are the commonest sites. Radiographs and other imaging findings are not specific. A large soft tissue component and decreased matrix mineralization are often seen.

5 Treatment

The patient outcomes in sarcomas are governed by an interplay of host, tumor and treatment strategies. The use of effective adjuvant modalities and appropriate function preserving surgery in a coordinated multimodality approach are of paramount importance. While multiagent chemotherapy and surgical excision is the standard of care in osteosarcoma, chondrosarcomas are largely treated with surgical excision alone.

6 Osteosarcoma

Chemotherapy is a vital component for the treatment of high-grade osteosarcoma and has increased survival substantially. Majority of the patients have micro metastasis at diagnosis and merit chemotherapy to optimize outcomes. A handful of chemotherapeutic agents are active in osteosarcoma, namely, doxorubicin, cisplatin, ifosfamide, high-dose methotrexate (HDMTX) and etoposide. However, it has been shown that the first three drugs have response rates from 26% to 43%, while etoposide had only 4% activity as a single agent.

6.1 Tumor Kinetic Principles and Cell Kill Models

Tumor comprises proliferative as well as dormant cells. Chemotherapeutic agents kill the proliferative pool, and doses and scheduling of drugs can significantly affect tumor lysis. Dose-intensity actually is defined by the drug delivery over a defined time and is derived by a formula as dose according to body-surface area mg/m^2 divided by chemotherapy completion time. This can be enhanced either by increasing drug dose or decreasing the total time to complete treatment. Various options are prevalent in practice to increase the dose-intensity with varied biologic and clinical implications Giving drug "A" at dose "B" 3 weekly results in dose intensity "value" of B/3 per week; doubling the dose yields an intensity of 2B/3; however, prolonging the cycle interval to 6 weeks yields an intensity of 2B/6 which equals a value of Y/3 and is lesser despite increasing the dose. Notably, an increased dose is not directly proportional to increased efficacy. Rather, there are several factors which determine the treatment effect inclusive of the respective cell kill from each chemotherapy dose and the overall treatment time(frequency of cycles) to deliver the cumulative chemotherapy dose and the pace of tumor repopulation interspersed between the chemotherapy cycles.

Another approach to increase the treatment effect is dose density, i.e., same dose intensity is maintained with the drug being delivered at shorter time intervals. This is found to be more effective due to the reduced incidence of tumor repopulation by surviving cells and the decreased possibility of development of drug resistant clones [18]. For example, if dose B is delivered biweekly, it will have a dose-intensity of B/2 which in turn would be similar to the doubled dose (dose 2B) if delivered once in every 4 weeks. The first strategy will still be superior with regard to dose density, and at the top of the dose–response curve, as the treatment interval is extremely important.

Similarly, sequential noncross-resistant chemotherapy cycles lead to higher cytotoxic effect as they are more dose dense. Notably, human solid tumors follow a Gompertzian growth pattern rather than log-kill model wherein the growth rate is inversely proportional to the size of tumor and hence decreases with increasing tumor size, up to a certain mass/volume and essentially plateaus there [19]. Likewise, tumors regrow fast post-suboptimal therapy, and hence, tumor eradication will not be achieved, which could have been the case in liquid malignancies which follow a simple log kill model. The log kill model was the first significant proliferation model described in oncology, which hypothesized that enough individual drug doses used in enough number of cycles would kill a significant percentage of tumor cells (if not all), and might cure cancer. This formed the basis of adjuvant chemotherapy regimens of the earliest generation. However, this has not been proven in all cancers, perhaps due to tumor heterogeneity with chemo sensitive cells interspersed with slowly growing resistant clones. To circumvent this issue, different permutation combinations of drugs are needed. Combinations could potentially affect efficacy due to dose modification of individual drugs. Chemotherapy cycles with alternating drugs (rather than sequential)("A" then "B" then "A" and so on) lengthen the interval between drug delivery and hence is potentially detrimental. This hypothesis was proposed by Norton and Simon that treatment should be first directed toward the dominant, rapidly proliferating cells and then toward the dormant, slowly growing resistant cells. This sequential pattern of therapy (wherein every "A" would be delivered first and then every "B" followed—i.e., AAAABBBBB), is inherently more dose-dense and was demonstrated superiority in various tumor types.

A meta-analysis demonstrated an improved survival in a multidrug regimen with three drugs in comparison to two drugs; additionally, it also noted that four drug regimen was not only not superior to three drugs rather was found to be more toxic [20]. The Cochrane review suggest inadequate evidence for or against HDMTX-based or non-HDMTX regimens (Table 2) [14, 15]. International guideline suggest toward using HDMTX in children and toward using non-

Table 3 Histological grading of osteosarcoma (adapted from the Ref. [49])

Salzer–Kuntschik grading	
Necrosis grade	Residual tumor cells
I	No viable appearing tumor cells
II	Single vital tumor cells or one vital cell cluster <0.5 cm
III	Vital tumor <10%
IV	Vital tumor 10%–50%
V	Vital tumor >50%
VI	No effect of chemotherapy
Huvos grading	
Necrosis grade	Residual tumor cells
IV	No viable-appearing tumor cells
III	Foci of viable tumor <10%
II	Tumor necrosis >50%
I	Little or no effect of chemotherapy

HDMTX among adults. HDMTX mandates complex pharmacokinetic monitoring, stringent hydration control and leucovorin administration in an inpatient setting [3]. It is more expensive and challenging to administer in resource constrained settings [21].

Chemotherapy-induced histological necrosis(HN) is considered the most robust prognostic marker and most widely accepted definition suggest that achievement of ≥90% necrosis signifies as good response. There are various standard grading systems to map the chemotherapy-induced HN; however, Huvos grading is widely accepted (Table 3) [22, 23].

Good responders, i.e., those who achieve a grade III or IV HN (Huvos grading), had superior outcomes. There were attempts to convert fate of poor responders by addition of chemotherapeutics in adjuvant phase, however, without success including in the large collaborative European and American Osteosarcoma Study Group (EURAMOS)-1 trial, wherein addition of ifosfamide and etoposide to existing three drug regimen did not improve outcome. Rather additional acute and chronic toxicities including second malignancies were observed [24].

Multiagent chemotherapy has substantially improved survival in osteosarcoma; however, since the last three decades, it has plateaued. Mifamurtide, an immunomodulator drug when added to chemotherapy has shown improvement in overall survival (albeit not event-free survival); however, it is not accepted as a standard due to lack of clarity about the trial design and results [25]. In EURAMOS-1 trial another immunomodulator drug interferon alpha-2b was tested in randomized fashion among good responders. Notably, the outcomes with MAP plus interferon alpha-2b were not superior to that of MAP alone arm, and hence, the strategy is not supported in standard osteosarcoma care [26].

Hence, a three-drug therapy essentially consisting of a cisplatin and adriamycin backbone along with either HDMTX or ifosfamide is recommended. Current evidence does not support changing chemotherapy on the basis of histologic response in localized osteosarcoma outside a clinical trial.

In low-grade (i.e., parosteal/juxtacortical and central) or intermediate-grade (i.e., periosteal) osteosarcoma, wide resection is the current standard. No adjuvant therapy is recommended. The indication for chemotherapy in periosteal (intermediate-grade) osteosarcoma is debatable.

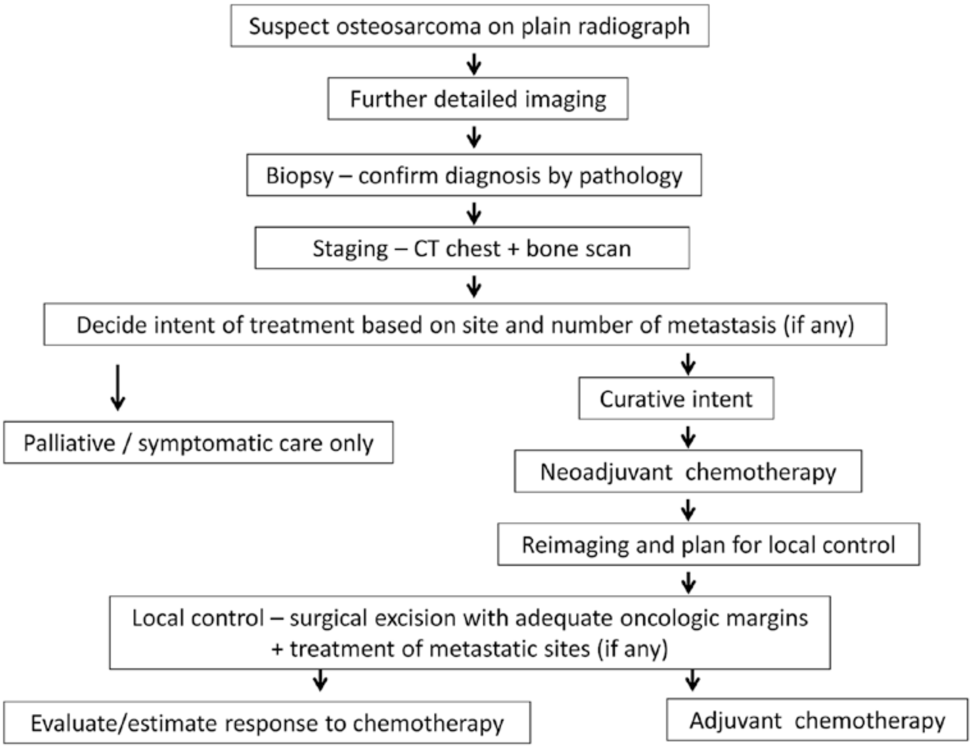
6.2 Our Institute Practice for Osteosarcoma

At Tata Memorial Centre, the histologically diagnosed osteosarcoma patients undergo standard staging workup and testing to assess optimal organ function to administer chemotherapy (Fig. 5). The workup comprises of complete blood count, renal function (by serum creatinine and radionuclide 99m technetium diethylenetriaminepentaacetic acid [DTPA] scan), liver function test, echocardiography and pure tone audiometry. Additionally, nutritional parameters are monitored at baseline, post NACT and ACT and periodically in-between based on treating clinician's decision and nutritionist's referral is carried out and appropriate corrective measures are practiced inclusive of intravenous and oral supplements.

The Standard "OGS-12" chemotherapy protocol comprises of four cycles of NACT and four cycles of ACT in sequential cycles, delivered every 21 days (Table 4). The cumulative doses of the drugs used are: cisplatin 600 mg/m^2, Adriamycin 300 mg/m^2, and ifosfamide 54,000 mg/m^2, over eight doublet cycles with universal primary growth factor prophylaxis and nutritional support as appropriate to enhance compliance [3]. Appropriate-dose modifications are carried out as clinically indicated for relevant higher grade hematological and/or nonhematological toxicities. Patients are assessed for optimal surgical procedure with adequate oncological margins after NACT is completed. Chemotherapy-induced histological necrosis on the surgical specimen is assessed using Huvos necrosis grading; however, here is no change of therapy based on this response metric [23].

6.3 Prognostic Markers in Osteosarcoma

Extremity location, good histological necrosis, low-grade tumors, no metastasis, low serum alkaline phosphatase, and LDH are good prognostic markers, while older patients (>40 years), secondary osteosarcoma, multifocal tumor and loss of heterozygosity of RB gene are identified as poor prognostic markers [27–30]. VEGF expression, Her 2 expressions, noninvasive imaging variables and compliance to therapy have also been suggested as potential prognostic indicators.



Suspect osteosarcoma on plain radiograph
Further detailed imaging
Biopsy – confirm diagnosis by pathology
Staging – CT chest + bone scan
Decide intent of treatment based on site and number of metastasis (if any)
Palliative / symptomatic care only
Curative intent
Neoadjuvant chemotherapy
Reimaging and plan for local control
Local control – surgical excision with adequate oncologic margins + treatment of metastatic sites (if any)
Evaluate/estimate response to chemotherapy
Adjuvant chemotherapy

Adriamycin 75 mg/m^2 (Divided over 3 days)						XXX	XXX	XXX	XXX
Ifosfamide 9 g/m^2 (Divided over 5 days)	XXX	XXX							

NACT Neoadjuvant chemotherapy, *ACT* Adjuvant chemotherapy

6.4 Metastatic Disease

Nearly ~20% of osteosarcoma patients are having macrometastasis at the time of presentation. Majority of these are pulmonary (60%–70% lung alone) while skip or distant bone metastases are variably reported (up to 20%–30%) [31].

The *de-novo* metastatic patient who presents with isolated pulmonary metastases merits aggressive multimodality care inclusive of surgery, chemotherapy and pulmonary metastasectomy [32]. Evidence suggests that young patients with good ECOG performance status and unilateral pulmonary metastases may have comparable survival to those with localized disease [33].

6.5 Recurrent Disease

Patients who relapse with lung metastases after completing first-line treatment are evaluated for metastasectomy depending upon disease-free survival and resectability. Disease-free survival is an important independent predictor for outcome and distant failure within 2 years is a poor prognosticator. However, those who achieve a second complete remission still have a relatively good chance with ~40% five-year overall survival [34].

The role of second-line chemotherapy in relapsed disease is not well defined, and the choice of therapy depends upon prior utilized drugs, disease-free interval and often includes ifosfamide ± etoposide ± carboplatin, HDMTX and a few other potent drugs (e.g., gemcitabine and docetaxel; sorafinib). In two large series with unresectable metastatic recurrence, chemotherapy has demonstrated limited increment in survival statistics. However, there was a meaningful benefit noted in resectable disease among one of the two studies. In symptomatic disease, chemotherapy on several occasions offers good palliation with clinically meaningful benefit. Newer agents with higher activity are an active area of research in recurrent osteosarcoma [35]. Certain antifolate agents like trimetrexate, have been investigated in relapsed scenarios. Patients who received conventional doses of ifosfamide (9 g/m sq), may be re challenged with escalated doses (14 g/m sq) and on a subsequent relapse again, to 17.5 gm/m sq^2 with meaningful responses (Jaffe N, unpublished data). However, due to potential nephrotoxicity, the 17.5 g/m sq. should be limited to three courses (one course every 4 weeks) in divided doses and with adequate hematological support for myelosuppression [36].

6.6 Role of Radiation in Osteosarcoma

Osteosarcoma is generally not considered a radiation-sensitive tumor. In situations where tumors are not amenable for surgical excision, radiation with or without concurrent chemotherapy may be considered. For patients with inoperable primary disease, high-dose external beam radiation therapy (70 Gy/35#/7 weeks @ 2 Gy/fraction) with conformal techniques like 3-dimensional conformal radiation therapy (3D-CRT) and intensity-modulated radiation therapy (IMRT) has resulted in satisfactory disease control without significant toxicity. Though still considered experimental, there is encouraging data on the role of proton and carbon ion therapy [37].

6.7 Future Directions

Osteosarcoma is a heterogeneous tumor, and hence, sequencing data did not show real benefit, and targeted therapies which focus on isolated aberrant signaling pathways are not successful. Tyrosine kinase inhibitors (TKI) have shown good activity in this challenging tumor, and potential kinase targets in osteosarcoma are VEGFR, PDGFR, mTOR and PI3K. An Italian phase 2 trial with oral TKI (sorafenib) along with everolimus has shown a clinically meaningful 45% 6-month progression-free survival, although the trial was statistically negative [38]. There is an unmet need and perhaps combined TKI therapy trial may enlighten us further. Osteosarcoma tumor cell ubiquitously expresses a cell surface marker GD2 and is a potential target. A large, multiplatform sequencing trial TARGET OS, from the National Cancer Institute, will provide right directions for future therapy. Despite that, there is some evidence that PD-L1 expression and tumor infiltrating lymphocytes are increased in osteosarcoma metastases and presence of tumor-associated macrophages are protective and associated with decreased metastasis, check point inhibitors are in an early phase of development and are considered experimental in this disease [39].

7 Chondrosarcoma

There is little role for systemic therapy in conventional chondrosarcomas. Dedifferentiated chondrosarcoma is associated with poor prognosis due to propensity to metastasize to bones and/or lung at presentation or early (within 12–18 months) [40]. Similar to osteosarcoma, adjuvant chemotherapy may be considered especially in the younger patients with no metastasis. At times, palliative use of cisplatin and doxorubicin may also provide meaningful clinical benefit especially in relatively good ECOG performance status in young patients. Another rare subtype is mesenchymal chondrosarcoma wherein surgical resection is primary treatment and adjuvant chemotherapy is similar to Ewing's sarcoma-type chemotherapy regimen. The drugs commonly used are vincristine, doxorubicin, cyclophosphamide, ifosfamide and etoposide. Dedifferentiated chondrosarcoma is another rare subtype and although it is not very chemo sensitive tumor, is often treated as a high-grade bone sarcoma often with a combination regimen with doxorubicin and cisplatin or ifosfamide and trabectedin [31].

Similar to osteosarcoma, chondrosarcoma too is considered a radiation-resistant tumor. In situations where in tumors are not amenable for surgical excision, radiation may be considered [41].

8 Surgery in Bone Sarcomas

8.1 Principles of Extremity Reconstruction

The goal of curative treatment in bone sarcoma is to achieve local control and decrease the risk of systemic relapse. While neo/adjuvant chemotherapy along with surgical resection is the mainstay in osteosarcoma, surgery alone is the norm for chondrosarcoma. Curative intent of treatment is when R0 resection (no residual microscopic disease) is possible in a safe manner. Long-term results have shown limb salvage to have similar survival as an amputation [42]. The local control rates have also been consistently high. Limb salvage is thus the standard of care when a tumor can be excised with an adequate oncologic margin while preserving satisfactory function. Three centimeters of marrow margin as measured on a T1 weighted image and a layer of normal tissue all around the tumor is generally adequate. An adequate soft tissue margin is difficult to quantify in millimeters in a consistent manner. Certain natural tissue barriers like intermuscular septum, deep fascia, periosteum, growth plate, cartilage, vascular adventitia and epineurium are more resistant to tumor invasion and act as sufficiently negative margins close to critical structures [43]. Adequate function postresection, acceptable cosmesis, minimal pain, ability to continue activities of daily living and superior function to an amputation prosthesis are the goals of a successful limb salvage surgery. Often limb salvage is combined with metastasectomy for curative intent. The common barriers to limb salvage are poorly placed biopsy incisions (transverse, crossing multiple compartments), involvement of a major vessel or major motor nerve that precludes reconstruction, a displaced pathological fracture with contamination of multiple compartments, intractable infection and inadequate remnant motor function after resection [6]. Some of these factors are relative contra-indications in the modern multidisciplinary era. A pathological fracture is not an absolute contraindication for limb salvage. It often heals after neoadjuvant chemotherapy and permits adequate oncologic resection allowing limb salvage [44].

Reconstruction after resection of bone tumors involves replacing the bone and soft tissue defects to allow good function and promote reliable tissue healing. Since most bone sarcomas affect the metaphyseal or epimetaphyseal region of the long bone, osteoarticular resection is needed. Intercalary resections are performed for predominantly diaphyseal or meta-diaphyseal tumors when joints on either side can be saved. For certain low-grade sarcomas, hemicortical resections (removal of part of bone circumference) achieve good local disease control [45]. Reconstruction is thus determined by the nature of the defect. Intercalary defects can be reconstructed by autografts or allografts, reimplantation of sterilized tumor bone (methods of sterilization have included autoclaving, microwave, pasteurizing, liquid nitrogen and extracorporeal radiotherapy) or intercalary prosthesis (Fig. 6). Osteoarticular defects are most commonly reconstructed with endoprosthesis. Modern endoprosthetic systems are large metallic segments that replace the excised

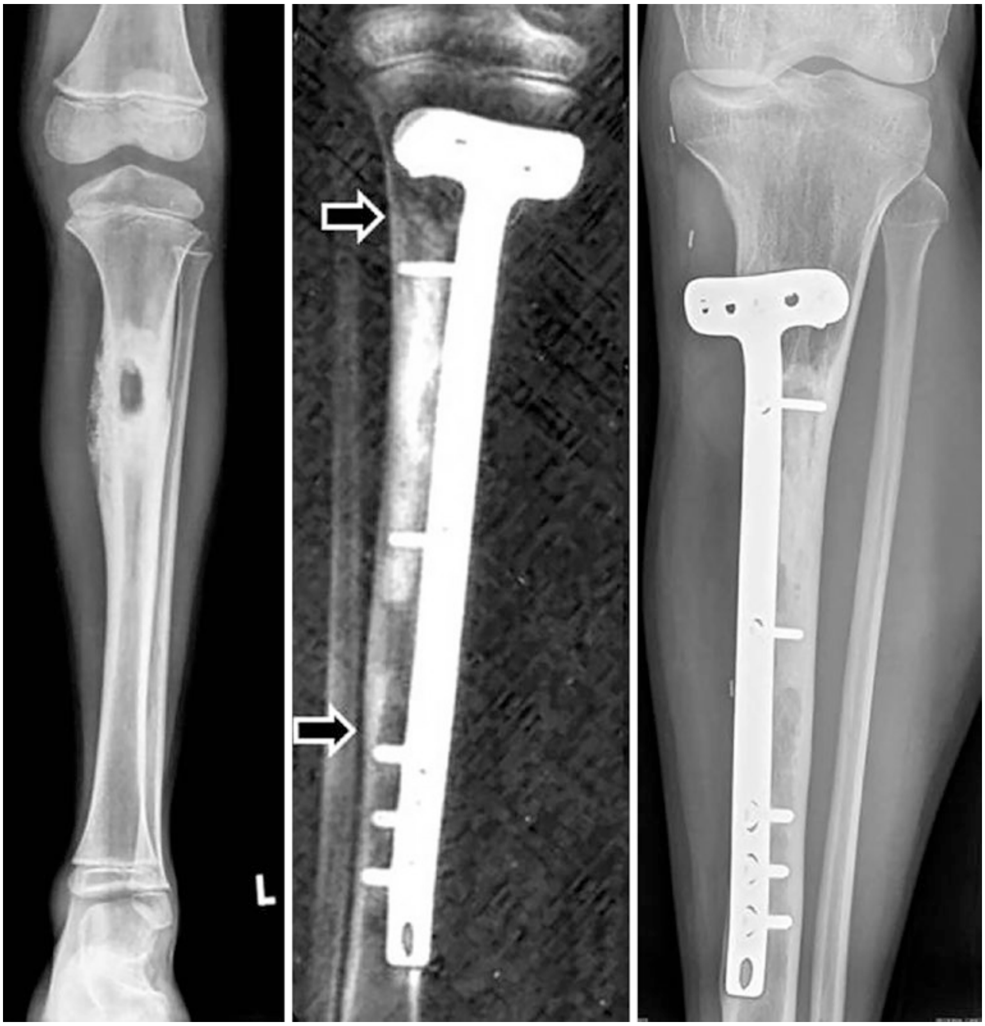

Fig. 6 Extracorporeal radiotherapy and reimplantation. Osteosarcoma of tibial diaphysis (left); resection and reimplantation (center arrows show osteotomy sites). Follow-up at 10 years with physeal growth having continued to occur (right)

bony segment and the adjacent joint (Fig. 7). They are modular and available off the shelf, thus allowing on-table reconstruction of defects of varying sizes. The rapid return to function and weight bearing, limited interference with adjuvant treatment in the form of chemotherapy or radiotherapy have made endoprosthetic systems the mainstay of extremity reconstruction. Allograft-prosthetic composites, osteoarticular allografts, joint fusion using bone grafts (arthrodesis) and rotationplasty are other methods of reconstruction after osteoarticular resection.

In children and adolescents an active growth plate that contributes to limb length is often involved or resected as tumor margin. This leads to significant limb length discrepancy at skeletal maturity. Rotationplasty though cosmetically not very appealing is an option that avoids the complication of limb length discrepancy. The most common site where rotationplasty is used is for tumors of the distal femur and proximal tibia. Patients undergo an en bloc excision of the distal femur and proximal tibia including skin and all surrounding soft tissues while maintaining the continuity of the neurovascular bundle. The bony limb continuity is then reestablished by fusing the tibia with the proximal femoral remnant after 1800 external limb rotation, thus allowing the ankle to function as the knee (Fig. 8). An expandable prosthesis can help overcome these problems. These are expensive, thus afforded by few in the LMIC (low–middle-income countries) and may need repeated revisions over the child's lifetime, thus increasing the risk of infection and other complications.

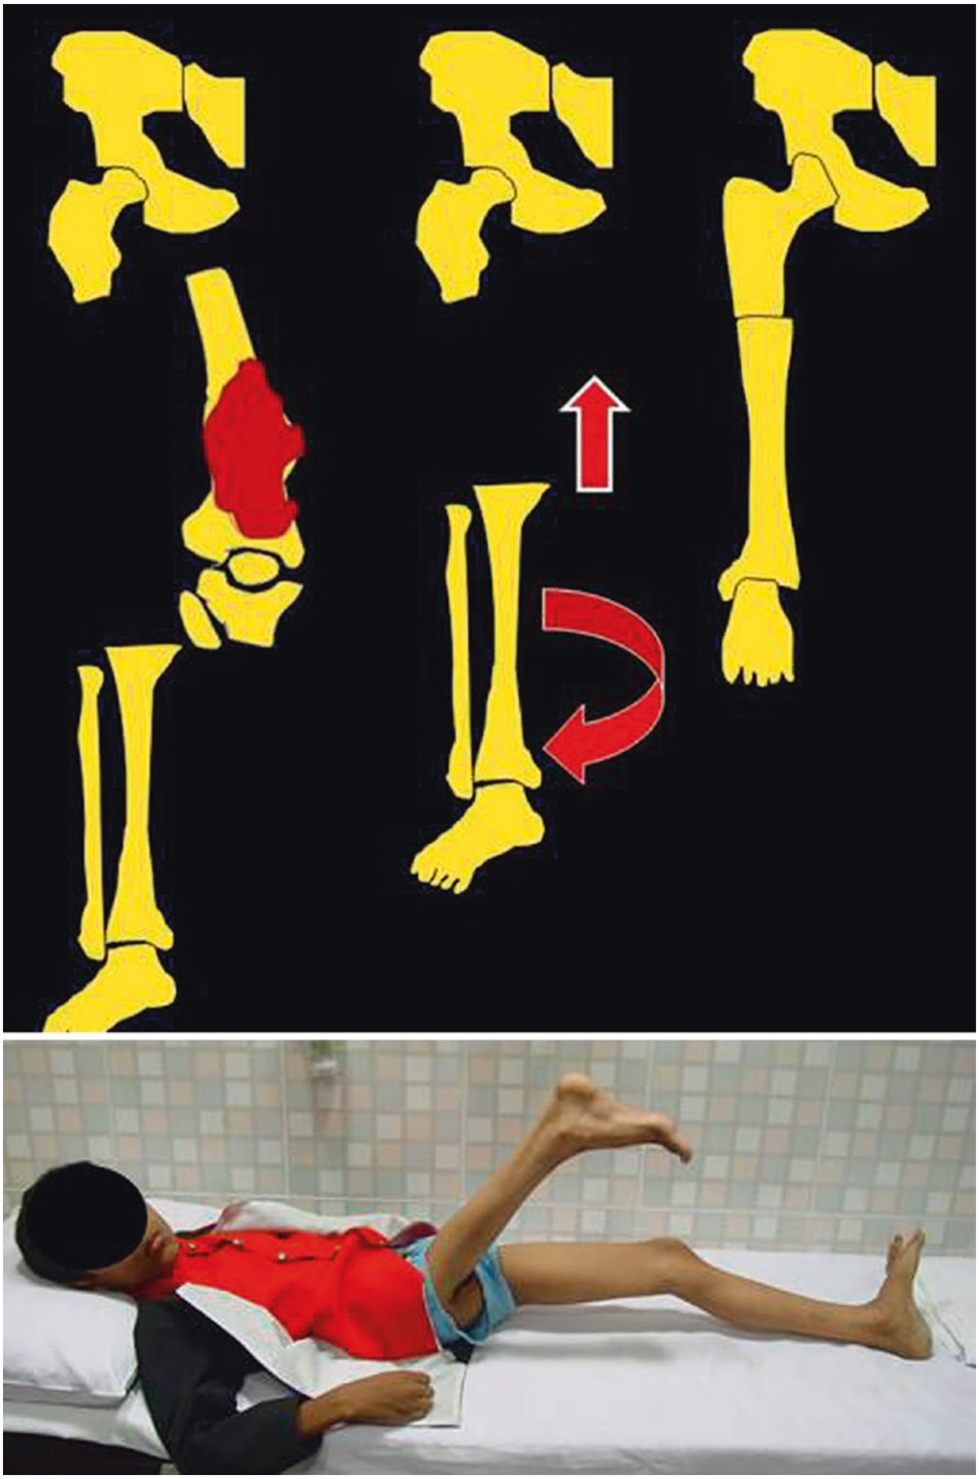

Fig. 8 Rotationplasty. Diagrammatic representation of a rotationplasty for a distal femur lesion demonstrating how the ankle functions as the knee

9 Surveillance and Follow-up

The aim of post treatment surveillance is to detect a recurrence or other treatment related toxicity (cardiotoxicity, ototoxicity, renal, fertility, function, second malignancy) early with the hope that early intervention will improve outcomes. It is unclear if aggressive surveillance modalities improve outcomes. Increased frequency of clinic visits and investigations is a huge resource, time and logistic burden. Another concern is cumulative radiation exposure. Most guidelines (NCCN, ESMO) recommend a 3–4 monthly follow up in the first 2 years, 6 monthly until 5 years and annually subsequently until year 10. Each visit involves a thorough clinical exam and history, radiograph of the operated area and a chest X-ray, and organ toxicity directed investigations. The only published on-inferiority randomized trial (TOSS) did not demonstrate a difference in outcomes with a lesser frequency of follow up (3 vs. 6 months) or modality of chest metastasis surveillance (CXR vs. CT) [46]. This study and other reports note that the majority of local recurrences are detected by the patient, and thus, pick up of asymptomatic radiologic local recurrence is unlikely. Once a recurrence is confirmed with a biopsy, cancer appropriate staging modality is used.

Apart from disease recurrence, it is essential to identify and manage other system toxicities as they have a significant impact on quality of life. It is best to have a dedicated clinic for long-term survivors whose concerns are different and not limited to disease status. Psychosocial support is an important part of surveillance, especially in the children, adolescent and young adult population.

TNFα	Tumor necrosis alpha
USG	Ultrasonography

1 Introduction

Soft-tissue sarcomas (STS) are rare heterogeneous tumors of mesenchymal origin arising in connective tissues, representing less than 1% of adult malignancies [1]. Due to their varied subtypes, they are a challenge to diagnose and treat. Sarcomas are classified according to the "World Health Organization Classification of Tumours of Soft Tissue and bone" providing universal nomenclature for use worldwide. Each subtype of STS has common clinical, therapeutic and prognostic features. Extremities are the most common site for STS accounting to up to 60% followed by trunk (19%), retroperitoneum (15%) and head and neck (9%) [2]. Approximately 80% arise in soft tissue and rest from connective tissues within the bone. The etiology of most STS is still unknown. In few cases, genetic and environmental factors such as exposure to chemicals (e.g., vinyl chloride, arsenic), exposure to radiation, viral infection (Herpes virus), immunodeficiency (Epstein–Barr virus), prior injury (scars, burns), chronic tissue injury, neurofibromatosis and certain germ line mutations (Li–Fraumeni syndrome [p53 mutations], RB1 gene mutations) [2, 5] can lead to few variants of STS. Given their low incidence, most clinicians and pathologists have limited experience in their presentation, which can lead to delay in diagnosis and treatment [3, 4]. The overall 5-year survival rate for STS in extremities is 65–75% [5]. In this chapter, we outline the current principles of diagnosis and treatment protocols for STS.

2 Incidence and Epidemiology in India and Globally

The National Cancer Intelligence Network (NCIN) reports that the incidence of STS is approximately 45/million population per year (NCIN) [6]. In a study conducted at Tata Memorial Hospital over a period of 1 year, out of all the malignant lesions presented to bone and soft-tissue department (1382), 30% (587) were STS [7]. As most of the soft-tissue lesions are intervened by community surgeons, it is difficult to get an exact incidence.

3 Clinical Presentation in India and Globally

Majority of STS occur in adults (94% >20 years age), and apart from alveolar soft part sarcoma and leiomyosarcoma, all other subtypes have male predominance (1.5:1) [8]. Extremities account up to 60% of STS with lower limb being a more common location than upper limb with a distribution

of 28% and 12%, respectively. Thigh is the most common site in the body accounting for 44% of all extremity STS [9].

Most common presenting complaint of STS is a painless, progressively increasing mass. At times, the patient may present with constitutional symptoms such as fever and/or weight loss. Some present with pain or symptoms associated with compression by the mass such as paresthesias or edema in an extremity. In case of pelvic and retroperitoneal sarcomas, they can present with a noticeable lump in the abdomen, increasing abdominal girth, pain, bleeding (hematemesis, melena, anemia) and obstruction. Superficial STS may present with fungation and bleeding.

Diagnosis of sarcomas of extremities is early compared to those in deep seated locations such as pelvic [10]. In developed countries, the presentation may be early compared to countries such as India where most of them presenting in advanced stages due to late presentation owing to ignorance and belief in other modalities of treatment other than modern medicine.

STS metastasize commonly to lung, and the patients can present with cough, shortness of breath, hemoptysis, pain or discomfort in chest and pleural effusion. Metastasis to bone is rare, and the most common complaint is pain [11].

4 Evaluation and Work-up

Evaluation of an STS involves detailed clinical examination, imaging to stage disease local and systemically and histopathological confirmation of subtype. Clinical evaluation includes estimation of the size of the lesion, location (superficial/deep), mobility and consistency. Palpation of the mass will help in determining the relationship to other anatomical landmarks. Local tenderness may be a sign of an inflammatory lesion. Pseudoaneurysm/vascular lesion can be ruled out by palpation/auscultation. A positive Tinel sign would indicate a nerve sheath tumor. Proximal draining lymph nodes should be examined for any lymphadenopathy. A soft-tissue mass exhibiting any of the following four clinical features should be considered to be malignant until proved otherwise: (1) Rapid increase in size, (2) size >5 cm, (3) location deep to the deep fascia, or (4) pain. The risk of malignancy increases with each factor with increasing size being best individual factor [12]. Benign or local grade lesion rarely metastasizes; hence, systemic evaluation may not be required.

4.1 Ultrasonography (USG)

Can be used for the evaluation of superficial STS and evaluate the size, depth and proximity to vital structures. It can also be used for screening of local draining lymph nodes to look for lymph node metastasis common in rhabdomyosarcoma, alveolar soft part sarcoma, clear cell sarcoma, epithelioid sarcoma, synovial sarcoma and angiosarcoma [13]. USG can act as a guide for tissue sampling in superficial masses.

4.2 Plain Radiograph

Plain radiograph has limited utility in evaluation of STS. The presence of calcification in a soft-tissue mass seen on a radiograph can point out toward a bone-forming sarcomas or synovial sarcoma [14].

4.3 Magnetic Resonance Imaging (MRI)

MRI is the preferred modality for evaluation of STS of extremities, trunk, head and neck as they provide multiplanar images with better spatial orientation. Signs such as deep-seated large mass, heterogeneous signal, surrounding edema and associated destruction of bone. In addition to stage the disease locally, MRI helps in planning biopsy approach and avoiding contamination of virgin compartments. They also help in surgical planning by determining the resectability of the tumor, extent of involvement and the proximity of neurovascular structures [15].

Lipomatous lesion is isointense to subcutaneous fat with no residual high signal intensity on T2-weighted fat-suppressed images and no internal complexity. A malignant transformation can be suspected when the lesion is greater than 10 cm, fat content being less than 75% and internal nodular enhancing components [16]. Tail sign on MRI can help distinguish myxofibrosarcoma from other myxoid-containing tumors [17]. Synovial sarcoma can be infiltrating or well defined. It has low signal intensity on T1-weighted images and heterogeneous signal intensity on T2-weighted images due to areas of necrosis, hemorrhage and calcifications. Reactive periostitis of the adjacent bone can be seen in 11–20% of our cases [18].

4.4 Computed Tomography (CT)

Though its role in local evaluation in extremities is less, non-contrast CT of the chest is essential to look for pulmonary metastasis which occur in approximately 10% of patients at presentation [10]. CT is the imaging of choice in retroperitoneal sarcomas or in cases where the lesion shows calcifications or cortical destruction. For deep seated lesions and heterogeneous lesions, CT or ultrasound guidance helps in targeting the most representative region [19].

4.5 Positron Emission Tomography-Computed Tomography

PET and PET CT are not routinely recommended for initial workup of STS [20]. PET/CT may be more useful in cases with recurrence of STS [21] and in suspected MPNST in a case with neurofibromatosis [22]. NCCN guidelines state that PET scan may be useful in prognostication, grading and determining response to neoadjuvant chemotherapy in STS [23]. As this study is based on a single institute study, the clinical utility of PET prior to surgical treatment is still unclear [24].

4.6 Recommendations for Local Evaluation

- Local MRI
- CT for retroperitoneal sarcomas

4.7 Recommendations for STAGING

- Non-contrast CT thorax
- USG of local draining lymph nodes
- MRI brain/spine in angiosarcoma and ASPS
- Whole body MRI + noncontrast CT thorax/CT thorax + abdomen + pelvis + MRI spine for myxoid liposarcoma

4.8 Biopsy

Histologic diagnosis of a soft-tissue mass is the gold standard for treatment planning. Biopsy should be done by the surgeon who will be doing final resection or should be done by someone aware of principles of treating sarcomas. Poorly placed biopsy scars can hinder with limb salvage procedures or may result in extensive surgery and increase morbidity. Core needle biopsy using a gun is the most preferred method [25]. CT or USG guidance can assist in deep seated lesions or to target a specific area in a heterogeneous lesion [19]. In cases where sample obtained by core needle biopsy is inadequate or not representative, incisional biopsy is considered for additional material. This material can be further used for tissue banking and research. Excision biopsy can be recommended for lesions <3 cm in size, superficial to deep fascia and away from critical structures [26] (Fig. 1). FNAC is not recommended in initial diagnostic evaluation of STS as it has a lower diagnostic accuracy, may not provide histologic subtypes or grade of sarcoma [27]. However, it has a role in confirming disease recurrence [28].

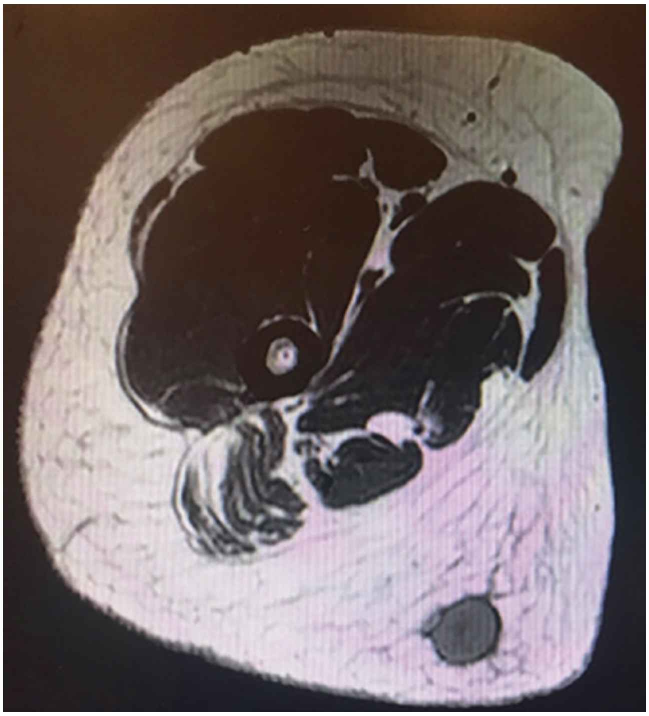

Fig. 1 Indication for excision biopsy

5 Pathology

WHO classifies them into more than 50 different histologic subtypes. The diagnosis of STS is based on the morphology. Immunohistochemistry (IHC) and monoclonal antibodies have been a major breakthrough in diagnostic evaluation for the pathologists. Fluorescent in situ hybridization (FISH) or reverse transcription polymerase chain reaction (RT-PCR) can be done to determine the molecular pathogenesis and confirm the histological diagnosis and also to identify subtypes within major histologic categories [29].

The tissue of origin is identified based on the immunohistochemical staining. The commonly used IHC is outlined in the Table 1.

They are either grouped according to the tissue of origin (e.g., liposarcoma, synovial sarcoma, angiosarcoma) or based on the architectural pattern (e.g., alveolar soft part sarcoma, epithelioid sarcoma). The common ones are outline in the Table 2. Most common subtypes are liposarcoma (15%), leiomyosarcoma (25%), synovial sarcoma (10%) and malignant peripheral nerve sheath tumors (6%) [2]. At Tata Memorial Hospital, synovial sarcoma was the most common histology (22.5%) with 24% being metastatic at presentation, followed by spindle cell sarcoma in 18.5% cases with 31% being metastatic at presentation. Soft-tissue Ewing sarcoma was in 12% of the cases with 50% of them having metastasis at presentation [7].

The commonly used histological grading system for bone and STS is the Fédération Nationale des Centres de LutteContre le Cancer grading system [30].

Table 1 Histology-specific IHCs

Desmin	Rhabdomyosarcoma, leiomyosarcoma
S100 antigen	Clear cell sarcoma, MPNST
Cytokeratin	Synovial sarcoma, epithelioid sarcoma
Factor VIII antigen	Tumors of endothelial origin

Table 2 Tumor types based on origin

Tumor Types	Subtypes	
	Benign	Malignant
Adipose	Lipoma	Well-differentiated liposarcoma Myxoid liposarcoma
Fibrous	Nodular fasciitis Deep fibromatosis	Fibrosarcoma Inflammatory fibrosarcoma Postradiation fibrosarcoma Cicatricial fibrosarcoma
Cartilage and bone forming	Extraskeletal chondrosarcoma	Extraskeletal osteosarcoma
Skeletal muscle	Rhabdomyoma	Alveolar rhabdomyosarcoma Embryonal rhabdomyosarcoma Ectomesenchymoma
Smooth muscle	Leiomyoma	Leiomyosarcoma Epithelioid leiomyosarcoma
Vascular	Hemangioma	Angiosarcoma Hemangioendothelioma Hemangiopericytoma
Nerve sheaths	Schwannoma Neurofibroma	Malignant schwannoma Neuroepithelioma Malignant granular cell tumor Malignant peripheral nerve sheath tumor
Synovial tumors		Synovial sarcoma Malignant giant cell tumor of tendon sheath
Pleomorphic tumors		Myxofibrosarcoma Angiomatoid fibrous histiocytoma

6 Staging

The staging system primarily used for STS is the American Joint Committee on Cancer (AJCC) or Enneking musculoskeletal tumor society staging system [31, 32]. AJCC grades them based on the size, nodal and distant metastasis nature, whereas Enneking uses the location of the tumor apart from grade and metastasis nature.

7 Referrals Including Genetic Counseling

Identification of an inherited gene alteration will not only help in early detection and cancer prevention, but also help in deciding the treatment protocols. Recognition of cancer genetic predisposition syndromes will allow patients and family members to under genetic testing and counselling to identify those at risk [33]. The patient usually have a family history of malignancies. Table 3 shows the common cancer predisposition syndromes associated with sarcomas [33].

Table 3 Familial inherited syndromes

Inherited syndrome	Inheritance	Genes	Chief clinical features	Associated sarcomas
FAP	AD	APC at 5q21-22	Thousands of colonic adenomatous polyps with colon cancer at age <40 years, osteomas, hepatoblastomas	Desmoid tumors
Li–Fraumeni syndrome	AD	TP53 at 17p13.1, CHEK2 at 22q12	Predisposition to early onset on multiple cancers, premenopausal breast cancer, STS, osteosarcoma, leukemias and adrenocortical carcinomas	Osteosarcoma, RMS, STS
Hereditary retinoblastoma	AD	RB1 at 13q14.2	Retinoblastoma, often bilateral and in early childhood (<5 years age)	Osteosarcoma, STS
Multiple osteochondromas	AD	EXT! at Bq24, EXT2 at 11p11	Multiple Osteochondromas	Chondrosarcomas
NF1	AD	NF1 at 17q11.2	Café-au-lait spots, neurofibromas, iris hamartomas (Lisch nodules), optic gliomas, skeletal abnormalities	MPNST, GIST, RMS

8 Principles of Management

Omnipresent in their site of origin, STS require multimodality treatment with patients managed at speciality centers (sarcoma referral centers) faring better than those treated elsewhere. Multidisciplinary team (MDT) consisting of pathologist, radiologist, surgeon, radiation therapists and medical oncologists form an integral part in treatment and decision making [34]. Table 4 shows the treatment plan for STS followed at Tata Memorial Hospital.

Histologically, four categories of margins have been described, namely: intralesional, marginal, wide and radical [35].

Intralesional: Margin runs through tumor leaving behind macroscopic disease. This can be done for palliative reasons or can be a result of unplanned excisions.

Marginal: Here, the surgical plane runs through pseudocapsule (reactive zone). As the reactive zone with tumor satellites is left behind, there are high chances of local recurrence rate.

Wide: The entire tumor is removed with a cuff of normal tissue measuring around 1–2 cm. If the soft tissue is adjacent to bone, it might warrant removal of a part of the bone to achieve wide margins.

Radical: This includes removal of the tumor along with the affected compartment. Though the chances of local recurrence are the least in radical resections, this is not routinely performed due to high morbidity. The most common indication for radical resection is local recurrence [36].

According to AJCC, the margins are classified as follows:

- R0—Margins free of disease
- R1—Microscopic tumor positive at inked border of the specimen
- R2—Gross tumor positive margin

There is another classification system, R + 1 mm classification [37], in which margins are classified as follows:

- R0—At least 1 mm of normal tissue between the tumor and inked margin
- R1—Tumor within 1 mm of the inked border
- R2—Grossly tumor positive margin

In a recently published study, the authors concluded that a negative but 1-mm margin may be adequate with multidisciplinary treatment. A planned close but ultimately positive margin along vital structures such as neurovascular bundles or bone increased risk for LR. Cases with inadvertent positive margins were associated with highest risk of local recurrence [37].

Table 4 How we do it at TMH

Grade	Depth	Treatment
Low	Superficial	Surgery
Low	Deep	Surgery (Ext RT only if margins close; <1 cm on gross intraop findings or if microscopic margins +)
High	Superficial/deep	Surgery + Brachy + Ext RT NACT—In metastatic cases/ borderline resectable chemosensitive tumors

9 Surgical Management

The standard principle is wide excision which refers to removal of tumor with rim of normal tissue. In high-grade tumors, to avoid local recurrence, resection should be done beyond the reactive zone. Usually a margin of 2 cm is considered adequate for STS. Here, Kawaguchi's concept of barrier effects is an effective reference for local planning [38]. Thick barriers such as iliotibial band, presacral fascia, periosteum of infant or a child and joint capsule are given weightage of 3 cm of normal tissue. Weaker membranous tissue of muscle fascia, the periosteum of an adult, vessel sheath and epineurium are considered thin fascia, which are considered equal to 2 cm of normal tissue. In cases where the tumor is adhered to the membranous barrier and the outer surface still retains its original luster, then 1 cm is deducted from its original value, which should be compensated for by including a cuff of normal tissue.

If surgery is the sole modality of treatment, the margin should be at least 1 cm in all directions or include a fascial barrier. In cases where the tumor is close to vital neurovascular structures, marginal excision combined with adjunct radiotherapy can be performed. In patients presenting with unplanned positive margin resections, re-excision should be planned if complete clearance can be achieved.

Macroscopic residual disease leads to poor outcomes even with additional postoperative radiotherapy [39]. Unresectable tumors and borderline resectable tumors (because of size or close to vital structures) can be subjected to neo-adjuvant chemotherapy or radiotherapy or both based on their histology [40]. When the mass is close to vital anatomical structures (major nerves or vessels), a planned positive resection can be done or upfront resection and reconstruction can be planned [37]. The aim of preoperative radiotherapy is to devitalize the margins of an anticipated marginal excision (Fig. 2).

Resections associated with compartectomy or significant soft-tissue loss will need reconstruction with free or pedicle muscle transfer. In STS cases wherein an unplanned excision was done (Whoop's excision), tumor bed excision should be considered with postoperative radiotherapy (high-grade cases) [41].

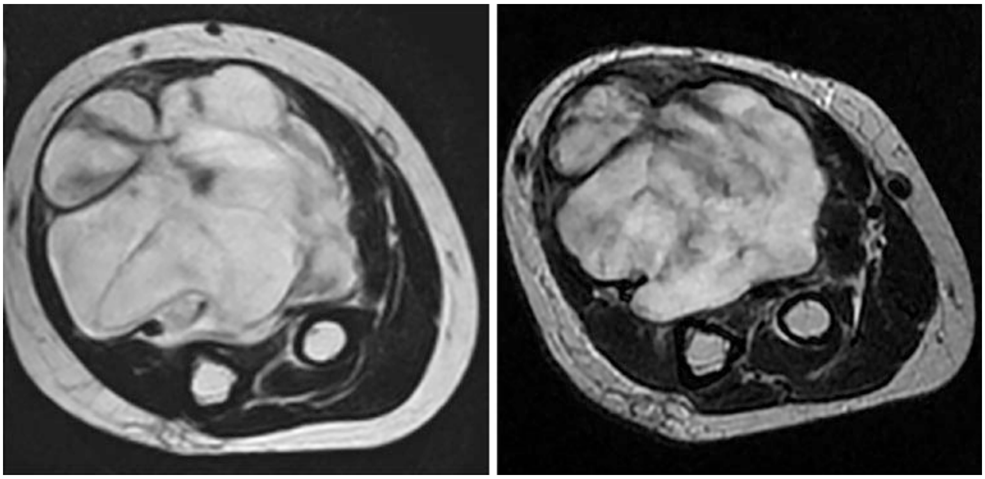

Fig. 2 A 25-year-old patient with a synovial sarcoma of the forearm close to the neurovascular structures. MRI images showing pre-RT and post-RT images

Despite multimodality treatment, sometimes localized tumors which cannot be resected completely may need an amputation to minimize the distant relapse. Amputation can also be offered in patient with multiple relapses, untreatable pain, bleeding or fungation [10].

10 Medical Management

Histology of the tumors helps deciding the role of chemotherapy in STS [42], but routine use in STS remains inconclusive [12]. High-grade tumors have the greatest tendency to metastasize, and such patients are most likely to benefit with chemotherapy [10]. The decision for preoperative chemotherapy should be a multidepartmental joint clinic decision. High-grade tumors which are borderline resectable and tumors wherein radiotherapy is not feasible qualify into this category. Neoadjuvant chemotherapy helps in assessing the histologic response to chemotherapy in an excised tumor allowing for detection of poor responders who may need an altered management [43].

To date, the largest trial of adjuvant chemotherapy for STS has failed to demonstrate any clear benefit from chemotherapy in local control, relapse-free survival or overall survival in patients treated with adjuvant chemotherapy [12]. The improved survival can be attributed to improved surgical techniques and increased use of adjuvant radiotherapy. As per NCCN guidelines [23], it is suggested that the need for adjuvant therapy be individualized on case to case basis. The other factors to be taken into consideration are patients performance status, comorbidities, disease location, tumor size and histologic subtype. Based on the meta-analysis from the Sarcoma Meta-Analysis Collaboration [44], a treatment regimen consisting both doxorubicin and ifosfamide significantly prolonged survival in patients post resection of extremity sarcomas. Adjuvant chemotherapy provided, small but definite risk reduction in local recurrence, distant recurrence and overall recurrence [44].

Table 5 Chemosensitivity of STS

Chemotherapy integral to management	Ewing's sarcoma family tumors Embryonal and alveolar rhabdomyosarcoma
Chemosensitive	Ewing's sarcoma family tumors Embryonal and alveolar rhabdomyosarcoma Desmoplastic small round cell tumor Synovial sarcoma Myxoid/round cell liposarcoma Uterine leiomyosarcoma
Moderately chemosensitive	Pleomorphic liposarcoma Epithelioid sarcoma Pleomorphic rhabdomyosarcoma Leiomyosarcoma Angiosarcoma
Relatively chemoinsensitive	Malignant peripheral nerve sheath tumor Myxofibrosarcoma Dedifferentiated liposarcoma Clear cell sarcoma Endometrial stromal sarcoma
Chemoinsensitive	Alveolar soft part sarcoma Extraskeletal myxoid chondrosarcoma

Table 5 shows the chemosensitivity of various STS [12].

10.1 Isolated Limb Perfusion

Isolated limb perfusion can be useful to downgrade the tumor and facilitate excision of STS in the extremities. The technique involves the use of local high-dose chemotherapy (melphalan), tumor necrosis alpha (TNFα) and hyperthermia. Using arterial and venous cannulation and a tourniquet, the affected limb is exposed to high quantities of these substances and has shown to shrink the tumor [45].

11 Role of Radiation in the Management of Soft-Tissue Sarcomas

Radiotherapy is an important adjunct to surgery for optimal local control and making limb salvage feasible. It can be in the form of preoperative radiotherapy or adjuvant radiotherapy. Adjuvant radiotherapy remains the most common form of radiation used for these tumors. The role of adjuvant radiotherapy was established more than three decades back, when three randomized controlled trials reported improvement in local control when offered as a part of limb salvage treatment [46]. The landmark NCI trial reported that the addition of adjuvant radiotherapy reduced local recurrences whereas the overall survival was similar to patients undergoing limb sparing surgery only [46]. Although the benefit was seen more in high-grade tumors, low-grade tumors also showed a significantly lower probability of local relapse [46]. A 20-year follow-up of the same study confirmed the above findings of excellent local control with acceptable treatment-related morbidity and no statistically significant improvement in overall survival [47]. Recent publications with large patient numbers have reported that adjuvant radiotherapy is associated with improved overall survival [48]. Low-grade, small (T1) tumors with negative margins can be treated with wide local excision alone; however, low-grade, T1 tumors with known adverse factors (like positive margins) and all high-grade, T2 tumors would benefit from the addition of radiation [46].

Adjuvant radiotherapy can be in the form of external beam radiotherapy (EBRT) or perioperative interstitial brachytherapy (BT). BT has been demonstrated to be an effective method of delivering adjuvant radiotherapy and has the benefit of shorter overall treatment time and smaller treatment volumes as compared to EBRT (Fig. 3) [49]. However, because it is a complex and labor-intensive technique, it is relatively less used. Though most of the Centre's practice conventional EBRT (Fig. 4), conformal radiotherapy in the form of intensity-modulated conformal radiotherapy (IMRT) has shown improved local control as well as favorable morbidity profile (Fig. 5) [50]. A nonrandomized comparative study from MSKCC reported local control significantly better with IMRT as compared to BT [51].

Preoperative radiotherapy has the potential of improving surgical margins and encouraging limb salvage in borderline resectable cases. The observed increase in the incidence of wound complications as compared to adjuvant radiotherapy and the imposed delay of surgical treatment, limits its use in our setting [52]. However, it is noteworthy that these acute wound complications though severe at times, are temporary. Contrary to this, the late complications of adjuvant radiotherapy like fibrosis, arthrosis and edema can be frequently progressive in nature [53]. A recently published national cancer database analysis report points toward higher rates of R0 resection for patients receiving preoperative radiotherapy and that negative surgical margins are associated with improved overall survival [54]. Utilization of improved radiotherapy

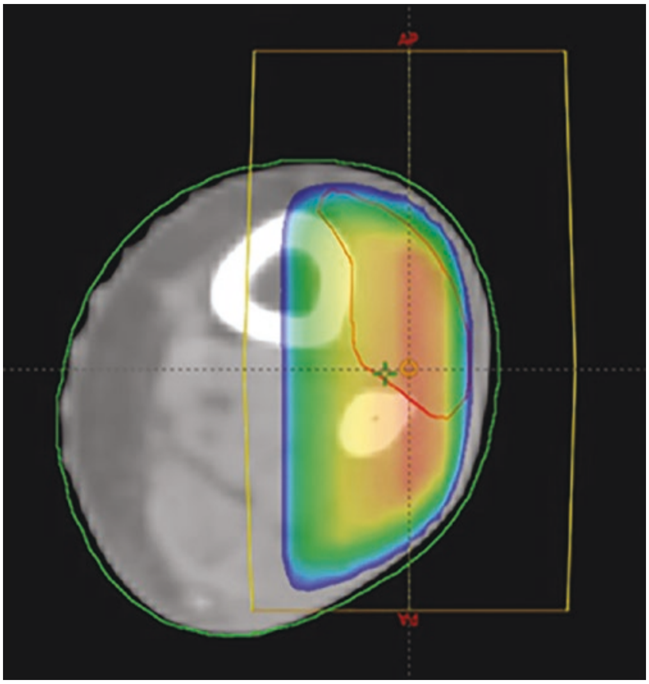

Fig. 4 Conventional radiotherapy dose distribution

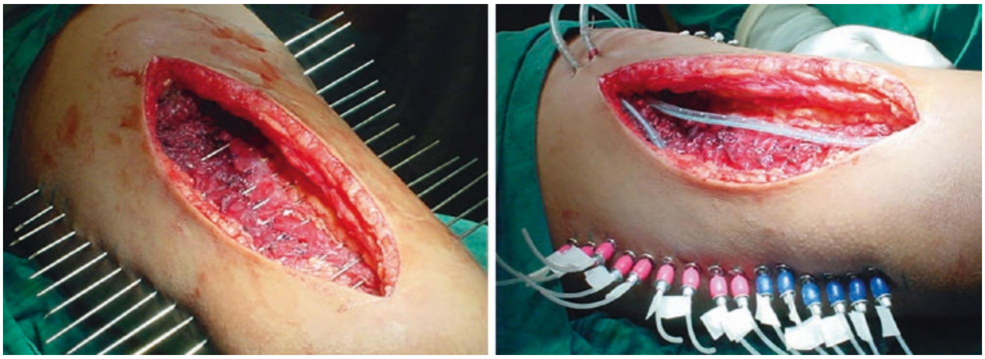

Fig. 3 Perioperative interstitial brachytherapy

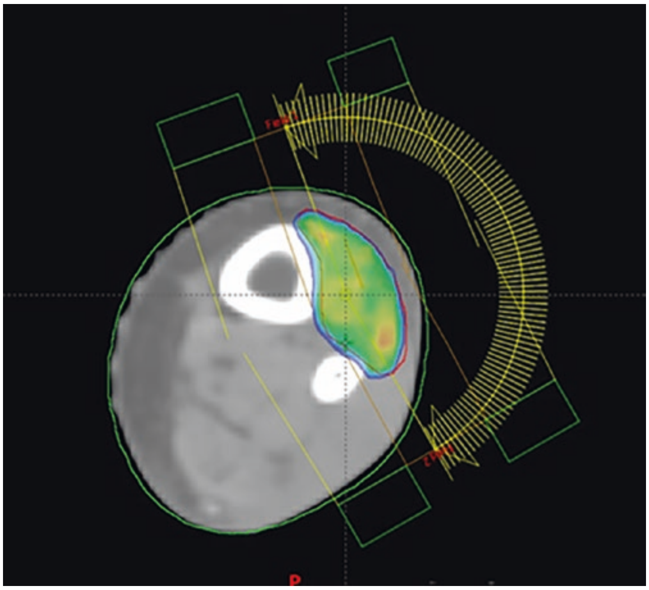

Fig. 5 Conformal radiotherapy dose distribution

technique (IMRT, image-guided and adaptive radiotherapy) is associated with significantly reduced incidence of wound complications [55]. The standard dose of radiation therapy ranges between 50 Gy/25#/5 weeks @ 2 Gy/fraction in the preoperative setting to 60–66 Gy/30–33#/6–7 weeks @ 2 Gy/ fraction in the postoperative setting.

As per NCCN guidelines, preoperative chemotherapy alone or preoperative radiotherapy alone or preoperative chemoradiation are all acceptable options. There are no data to support one over the other; if possible, these patients should be treated in context of a clinical trial.

12 Prognosis

Prognosis depends on grade, size, depth, age and histology of the tumor. There are well established nomograms that estimate the prognosis fairly well [56]. Local recurrence is related to grade, margins of excision and exposure to radiotherapy. In most cases, recurrences will arise within the first 5 years following treatment, and late relapses may occur in large tumors [57, 58].

13 Surveillance

There is no specific protocol for surveillance posttreatment due to lack of literature. The frequency and modality of imaging during flow-up remains controversial. Following a unique non inferiority trial conducted at our own institute we have concluded that a less intensive (chest X-ray) follow-up regime was not inferior to a more intensive regime (NCCT thorax) in patients treated for extremity sarcomas. In most cases, a chest X-ray at 6-month intervals and patient education regarding local examination of the surgical site will detect most recurrences without deleterious effects on eventual outcome [58]. Six-month follow-ups are advised for the first 5 years followed by yearly follow-up for the next 5 years.

14 Management of Recurrent Disease Including Specific Palliative Measures

Propensity for hematogenous dissemination is the most life-threatening aspect of sarcomas. Fifty percent of patients with high-grade sarcomas develop distant metastases and have a median survival of 12–19 months from diagnosis of metastases [59]. Though majority of patients who develop metastases are incurable, patient who can be treated with curative intent should be carefully selected. If the relapse is limited to local site, then the treatment would involve wide local excision with soft-tissue reconstruction procedures (depending on the extent of surgery). If the relapse is in the regional lymph nodes, nodal dissection is warranted with excision extending one level above the level of disease.

In cases with resectable pulmonary metastases, the reported 5-year survival is 25–40%. The recommended selection criteria for those undergoing pulmonary metastasectomy are as follows [60]:

- R0 resection should be feasible
- Primary disease should be controlled or controllable
- Absence of extrapulmonary metastases
- Physiological reserve in the patients to withstand the procedure

In patients with unresectable disease or with wide spread disseminated disease, chemotherapy is given with palliative intent with the goal of decreasing tumor bulk, symptomatic relief, better quality of life and prolonging survival. Apart from chemotherapy, surgery, radiotherapy and radiofrequency ablation can be considered in symptomatic metastases or in an attempt to prolong remission. Other drugs providing symptomatic relief included bisphosphonates or denosumab. It is advisable to involve specialists in palliative care to help benefit those who are critically ill.

How We Do It at TMC (Figs. 6 and 7)

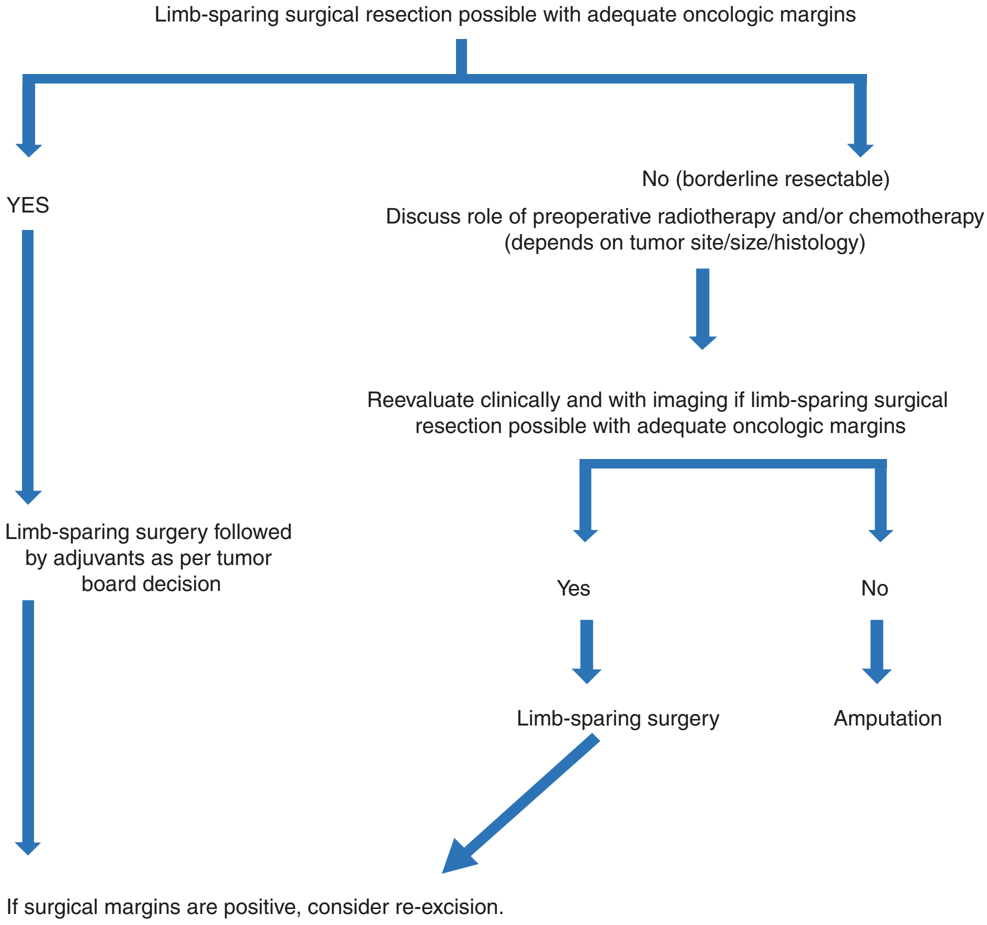

Fig. 6 Extremity soft-tissue sarcoma—nonmetastatic at presentation

Limb-sparing surgical resection possible with adequate oncologic margins
YES
No (borderline resectable)
Discuss role of preoperative radiotherapy and/or chemotherapy (depends on tumor site/size/histology)
Reevaluate clinically and with imaging if limb-sparing surgical resection possible with adequate oncologic margins
Limb-sparing surgery followed by adjuvants as per tumor board decision
Yes
No
Limb-sparing surgery
Amputation
If surgical margins are positive, consider re-excision.

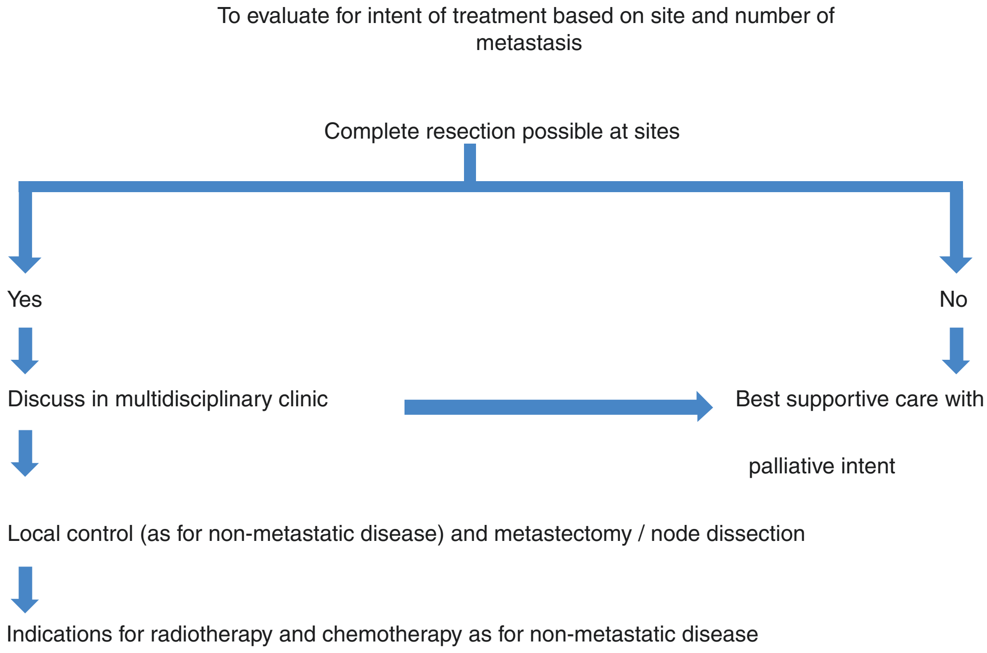

Fig. 7 Extremity soft-tissue sarcoma—metastatic at presentation

To evaluate for intent of treatment based on site and number of metastasis
Complete resection possible at sites
Yes
No
Discuss in multidisciplinary clinic
Best supportive care with palliative intent
Local control (as for non-metastatic disease) and metastectomy / node dissection
Indications for radiotherapy and chemotherapy as for non-metastatic disease

GPOH	German Pediatric Oncology and Hematology Group
IMRT	Intensity-modulated radiation therapy
LDH	Lactate dehydrogenase
MRI	Magnetic resonance imaging
PNET	Primitive neuroectodermal tumor
POG	Pediatric Oncology Group
RT	Radiation therapy

1 History

James Ewing, an American pathologist, described "diffuse endothelioma of bone," characteristically different from the then well-known osteosarcoma, in 1921 (2 years after the publication of the first edition of his cancer textbook), in the radius bone of a 14-year-old girl [1]. After the failure of initial treatment with Coley's toxin, the tumor was treated with 12,760 millicurie hours of radium every 2 weeks for three doses leading to "surprising disappearance" of the tumor at the end of 5 weeks. Further, Ewing distinguished his series of six similar cases of bone tumors (tibia, ulna, ischium, skull and scapula [aged 14–19]) from osteosarcoma as "A large portion or the whole of the shaft is involved, but the ends are generally spared, contrary to the rule with osteogenic sarcoma. The shaft is slightly widened, but the main alteration is the gradual diffuse fading of the bone structure. Bone production is entirely absent. The radiograph is therefore rather specific." Another eponym associated with Ewing Sarcoma is the Codman's triangle, the periosteal elevation and calcification associated with bone tumor, first described by the British Pathologist, Ernest Codman. Even after almost a century of its initial description, most of the characteristics described by James Ewing and Ernest Codman, based only on a few case reports, have withstood the test of time. Interestingly, it was Ernest Codman who coined the term "Ewing sarcoma."

Historically, Ewing sarcoma (ES) was also among the first solid tumors to demonstrate chemo-sensitivity in the 1960s [2–4]. The characteristic chromosomal translocation of EWS-FLI1 was identified in the 1980s and similar translocations in histologically distinct primitive neuroectodermal tumors helped consolidate them into a common family in the next decade [5–7].

2 Epidemiology

Ewing sarcoma is the second most common bone malignancy, after osteosarcoma. This is predominantly a disease of adolescence, characterized by a median age of presentation of 15 years and most cases occur in the second and third decade of life, with a slight male preponderance. The reported frequency in population younger than 20 years is 2.9/million [8]. The unusual predilection in the Caucasians is another striking characteristic of Ewing sarcoma (six times more frequent than African Americans) and is partially explained by the shortening of Intron 6, near the breakpoint region of EWS in African population [9].

Table 1 EWS gene rearrangement in Ewing sarcoma and other malignancies

Ewing sarcoma			
Partner of EWSR1	Chromosome	% of ES	Reference
FLI1 (Friend leukemia virus integration site 1)	11q24	85	[5]
ERG (ETS (Erythroblast transformation specific)-related gene)	21q22	10	[11]
ETV1 (E Twenty Six)	7p21	<1	[12]
E1AF (ETV4 or PEA3—Polyoma enhancer activator 3)	17q12	<1	[13]
FEV1 (Fifth Ewing variant)	2q33	1	[14]
Other malignancies			
Partner of EWSR1	**Chromosome**	**Malignancy**	**Reference**
PBX1 (pre-B cell leukemia homeobox 1)	1q23	Myoepithelial tumor	[15]
CREB1 (cAMP response element binding protein 1)	2q33	Clear cell sarcoma of soft parts	[16]
DUX4 (double homeobox protein 4)	4q35	Rhabdomyosarcoma	
WT1 (Wilms tumor 1)	11p13	Desmoplastic small round cell tumor	[17]
ZNF384 (Zinc finger protein 384)	12q13.31	Acute leukemia	[18]
DDIT3 (DNA-damage-inducible transcript 3)	12q13.3	Myxoid liposarcoma	[19]
NR4A3 (nuclear receptor subfamily 4 member 3) or MINOR (mitogen-induced nuclear orphan receptor)	9q31	Extraskeletal myxoid chondrosarcoma	[20]

3 Biology and Histology

Unlike Osteosarcoma, which is known to harbor astounding genetic heterogeneity, Ewing sarcoma is characterized by a relatively simple karyotype, most common being a reciprocal chromosomal translocation between chromosomes 11 and 22 (t(11;22)(q24;q12) in about 85% of cases [10]. The other possible translocations, involving the ews gene on chromosome 22 and leading to Ewing sarcoma, are described in Table 1, which together can be diagnostic for about 98% of Ewing sarcoma cases [11, 12]. Hence, the demonstration of EWSR1 break apart mutation, demonstrating *ews* gene rearrangement, by fluorescent in-situ hybridization technique, can be pathogenomic for majority of patients of Ewing sarcoma.

The classical EWS-FLI1 rearrangement results in the translocation of the 3′ portion of *fli1* (friend leukemia virus integration site 1) gene from chromosome 11 to the 5′ portion of the *ews* (Ewing sarcoma) gene on chromosome 22. The demonstration of this rearrangement correlates with the high expression of CD99 (MIC2), a cell surface sialoglycoprotein [21, 22]. A CD99 negative but t(11;22)(q24;q12) positive Ewing sarcoma has never been observed [23, 24].

Though the histogenesis of this tumor is still debatable, ES are among the small round blue cell tumors. The gross appearance of ES is that of a permeative, destructive growth in a bone with cortical infiltration, periosteal reaction and soft tissue extension. They have a fleshy, whitish appearance with variable tumor necrosis, cystic degeneration and hemorrhage [25]. Bone formation in response to chemotherapy may be visible but in much lesser proportion as compared to that in osteosarcoma. Extraosseous ES has similar morphology. They demonstrate a gradient of neuroglial differentiation; with poorly differentiated ES at one end and the more mature peripheral primitive neuroectodermal tumors (pPNET) at the other [1, 26, 27], though without any here-to-known therapeutic or prognostic significance. Strong diffuse membranous staining for cell-surface glycoprotein p30/32MIC2 (CD99) is characteristic of both and is present in 95–100% of the reported series, in addition to vimentin [28]. pPNET may show immunoreactivity for neuron-specific esterase (NSE), S-100 protein and Leu-7 [29]. Other Immunohistochemistry markers may be used to differentiate from neuroblastoma (positive for NSE, S-100 and Leu-7 but negative for Vimentin), lymphoma (positive for CD99 but also for leucocyte specific antigen CD45 (negative in ES), rhabdomyosarcoma (may be focally/weakly/cytoplasmic positive for CD99 but also positive for myogenin, myoD1 and desmin). Distinction from certain variants of synovial sarcoma (poorly differentiated small cell) may be difficult and molecular genetic testing for specific pathogenomic markers may be necessary [30].

4 Clinical Presentation and Staging

Ewing sarcoma cases have been reported in all age groups, but majority of the patients are adolescents at the time of presentation [31]. Pain, often loco-regional, is the predominant presenting complain, which characteristically does not resolve completely even during sleep [32]. Due to age associations, pain is often attributed to sports-related injuries or everyday activities or “growth spurts”. Pain, that is unexplained and not attributable to a defined trauma, lasting for more than a few weeks, continuing at night or with other unusual features, should prompt early imaging studies. The development of a visible mass or swelling follows pain in majority of patients. In ES of the pelvis, chest wall and the femur bone (most common sites of ES), mass may be indiscernible for a long time. Tumors of the vertebral compartment may present with symptoms of spinal cord compression, requiring urgent surgical and medical interventions.

The duration of symptoms before definitive diagnosis has been reported to be weeks to months, with a median of 3–9 months [33, 34]. Although, in a recent prospective study on a large cohort of patients, the duration to diagnosis did not affect survival in ES patients [35].

There are no blood, serum or urine tests that can specifically identify ES. Serum lactate dehydrogenase (LDH) may correlate with the tumor burden and hence prognosis.

About 85% of ES arise in the bones and in contrast to osteosarcoma, the flat bones of axial skeleton are more commonly affected [31]. In the long bones, ES classically arises from the diaphysis. Presentation with metastases (most commonly lungs, bone and bone marrow) occurs in up to 25% of patients. Metastases to lymph nodes, liver and brain are highly uncommon at presentation.

The initial investigation recommended is a radiograph in two planes, demonstrating osteolysis, periosteal elevation (Codman's triangle), wide zone of transition and a diaphyseal location. Magnetic resonance imaging (MRI) is superior (but may be more difficult logistically) to computerized tomography (CT) scans in delineating the relation to adjacent structures like nerves and vessels and the intramedullary extent of tumor, in addition to detection of skip lesions, all of which are crucial for local therapy planning. For the same reasons, imaging should include the entire bone and the joints proximal and distal to the lesion [32, 36–38]. All imaging should be done before any invasive intervention like biopsy.

The diagnosis of ES (or any bone malignancy) should never be ascertained without a biopsy. Incisional biopsy (core needle or open) should give adequate tissue for morphology, immunohistochemistry and molecular diagnosis and be considered to provide tissue for bio-banking for future translational research [39]. It is strongly recommended that initial biopsy be performed by the same surgeon who will later perform definitive resection of the tumor. This is to ensure that the biopsy tract can be excised in the final planned excision [40]. The soft tissue component (in the periphery of the tumor) in most bone malignancies is the ideal target for diagnostic biopsies, and deep sampling is not necessary. Diagnostic accuracy of core needle biopsies exceeds 95% and are superior to fine needle biopsy, which may not give sufficient material for cytogenetics, flow cytometry or gene profiling, when necessary [41].

The staging of ES entails looking for metastases in lungs, bones and bone marrow. A CT scan of the chest is mandatory to detect lung and pleural-based metastases. Conventionally, 99m-technetium whole-body radionuclide bone scans are used for detecting bony lesions, but fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET) has been demonstrated to be highly sensitive for picking up bone metastases, may be even more than whole-body MRI [42]. Bone marrow metastases (present in less than 10% patients at presentation) are conventionally detected by biopsies from both posterior superior iliac crests. Care needs to be taken to avoid inadvertent biopsies from the primary tumor of pelvic origin when looking for bone marrow involvement. An FDG-PET CT scan (including chest CT) is a one-stop staging investigation for lung, bone and bone marrow metastases, gaining evidence that will obviate the need for separate bone scan and invasive (painful) bone marrow biopsies. The detection of micro-metastases in bone marrow or of circulating tumor cells in absence of overt metastases is currently under evaluation in prospective studies for its prognostic significance and possible therapeutic interventions [43].

5 Treatment Philosophy for Ewing Sarcoma

ES is a systemic disease, even when overtly localized, requiring systemic therapy in addition to local treatment of the tumor. This is historically evident when more than 90% of ES patients died due to systemic metastases, with only surgery or radiation of the primary tumor [44]. Among the first-known solid tumors to demonstrate chemosensitivity in the 1960s, the evolution of multiagent chemotherapy, sequential learnings and gains in survival with optimization of various combinations, by multi-institute, multinational, co-operative group clinical trials, is exemplary. With the use of multimodality therapeutic regimens including multiagent chemotherapy, surgery and radiation therapy (RT), majority of patients with ES can be cured (localized ES—~75%, metastatic 10–40%) [45].

6 Evolution of Chemotherapy for Localized Ewing Sarcoma

Demonstration of chemosensitivity of ES to single agents (cyclophosphamide, actinomycin D, doxorubicin and ifosfamide) in the 1960s was followed by the advent of multiagent chemotherapy in the 1970s. Traditionally the transatlantic groups (North America and Europe) have approached similar questions with similar results with minor variations in philosophies. Table 2 shows the sequential chemotherapy trials over last 5 decades, their major results and the lessons learnt.

To summarize, the addition of doxorubicin and realization of the importance of early dose intensification characterizes the major gains in survival of patients with ES. The standard of care for the North American group remains the dose intense alternate VCD/IE backbone and the Europeans prefer the simultaneous VIDE-based chemotherapy regimens. Four to six courses of intensive chemotherapy is fol-

Table 2 Evolution of chemotherapy regimens in ES

Study	Reference	Therapy	Patients (*n*)	5-year EFS	Important lessons from the trial
Intergroup Ewing Sarcoma Study (IESS)					
IESS-I (1973–1978)	[46]	VAC	342	24%	
		VAC + whole lung irradiation		44%	Benefit of WLI
		VACD		60%	Definite benefit of addition of doxorubicin
IESS-II (1978–1982)	[47]	VACD – High dose	214	68%	
		VACD – Medium dose		48%	Benefit of aggressive cytoreduction and early doxorubicin dose intensity
INT-0091 (InterGroup POG + COG) (1988–1993)	[48]	VACD	200	54%	
		VACD + IE	198	69%	Addition of IE in localized disease improves survival but not in metastatic disease
Memorial Sloan Kettering Cancer Centre Studies (MSKCC)					
T2 (1970–1978)	[49]	VACD (adjuvant only)	20	75%	
P6 (1990–1995 and 1991–2001)	[50]	HD-CVD + IE	36 and 68	77% (2 years)	Dose intensification and good results in localized disease but no improvement in metastatic setting
St. Jude Studies					
ES-79 (1978–1986)	[51]	VACD	52	82% (<8 cm) 64% (>8 cm)	Tumor volume is an important prognostic factor
ES-92 (1992–1996)	[52]	VCDIE	34	78% (3 years)	Tumor size loses prognostic significance when treated with more aggressive chemotherapy
SFOP/France					
EW-88 (1988–1991)	[53]	VD + VD/VA	141	58%	Histological response to chemotherapy a better prognostic marker than tumor volume
United Kingdom's Children Cancer Study Group (UKCCSG)/ MRC Studies					
ET-1 (1978–1986)	[34]	VACD	120	41%	The most important prognostic factor was tumor site (extremities (52%) > axial (38%) > pelvic (12%))
ET-2 (1987–1993)	[54]	VAID	201	62%	High-dose alkylating agents improved survival
Cooperative Ewing Sarcoma Study Group (CESS)					
CESS-81 (1981–1985)	[55]	VACD	93		Prognostic significance of tumor volume (100 ml: 80% vs. 31%) and histologic response to chemotherapy (90%: 79% vs. 31%)
CESS-86 (1986–1991)	[56]	VACD (SR) VAID (HR)	301	52% (SR), 51% (HR)	Same as CESS-81 and addition of Ifosfamide (high dose) may improve outcomes in HR
CESS + UKCCSG – EI-CESS					
EI-CESS-92 (1992–1999)	[31]	VAID/VACD (SR)	155	68%/61%	Prognostic significance of stage, histologic response, type of local therapy
		VAID/EVAID (HR)	326	51%/61%	
AEWS-0031 (2001–2005)	[57]	VCD/IE + GCSF (standard vs. interval compressed)	587	65% vs. 73%	Interval compression is possible without increasing toxicities and improves outcome
Euro-Ewing 99					
1999–2006	[58]	Impact of EWS gene rearrangement	565		EWS/ETS fusion type is nonprognostic
1999–2005	[59]	Primary disseminated ES	281	3-year EFS 27% and OS 34%	Age, site of metastases and tumor volume-based risk score may help prognosticate and decide treatment intensity

Table 2 (continued)

Study	Reference	Therapy	Patients (*n*)	5-year EFS	Important lessons from the trial
2000–2010	[60]	VAC vs. VAI in good-risk ES (<10% viable tumor postchemotherapy and volume <200 mL)	856	3-year EFS 75% vs. 78%	Ifosfamide and cyclophosphamide are interchangeable in good-risk ES
2000–2015	[61]	BuMel ABMT vs. VAI in localized high-risk ES (>10% viable tumor postchemotherapy or volume >200 mL)	240	8-year OS 64% vs. 55%	Localized high-risk ES may benefit from BuMel-based ABMT intensification
Euro-Ewing 2012					
2014–2019	[62]	Comparison of Transatlantic approaches, Alternate VCD/IE (2 weekly) vs. VIDE (3 weekly)	640	3-year EFS 67% vs. 61%	Dose-intensive VCD/IE is more effective, less toxic and has shorter duration for all stages of ES. The new standard of care

VAC Vincristine, actinomycin, cyclophosphamide, *VACD* VAC + doxorubicin, *IE* ifosfamide, etoposide, *HD* high dose, *SR* standard risk, *HR* high risk

lowed by local therapy and then adjuvant chemotherapy (8–10 courses). The recently published results of the randomized comparison of the two approaches, the Euro-Ewing 2012 trial, suggests better efficacy, lesser toxicity and shorter duration of treatment with the dose intensive regimen. The most important tumor and host-related prognostic factors are age, tumor volume, site and presence of metastases apart from histologic response to chemotherapy, which in addition to being prognostic, has recently been shown to be predictive in high risk ES, with treatment intensification with BuMel-based ABMT [53, 61].

7 Local Therapy in ES

Though the biggest gains in survival in ES can be attributable to chemotherapy, cure is not feasible without appropriate local therapy. With the demonstration of radio-sensitivity of ES, RT remained the standard local treatment modality for some decades, but with improvement in modern orthopedic surgeries, aiming preservation of function with sustained improvements in survivals, the choice of modality of local therapy in ES has evolved significantly [62]. To date, there have been no randomized trials for comparison of surgery and RT as local therapy modalities for ES and due to inherent biases and complicated moral and ethical dilemmas involved, such a trial may not be feasible in the future, too.

The planning of optimal modality of local therapy in ES necessitates multidisciplinary efforts from the beginning of treatment. The importance of interdisciplinary cross-talk between experts from various teams cannot be undermined and has demonstrated impact on outcomes in multiple recent clinical trials [63, 64]. The optimal local therapy of ES should be individualized based on patient's age, site and size of tumor, relationship to surrounding vital anatomical structures, aiming at organ and function preservation without compromising disease control.

Surgery in ES aims at a complete, en-bloc resection of tumor with adequate margins. Preoperative RT has traditionally been used for patients with local disease progression during chemotherapy but more recently it has been considered to avoid an intralesional resection. The local failure rates are comparable between this approach and for those with negative margin surgery in more amenable lesions [62].

The choice of reconstructive options includes autologous bone grafts, structural bone allografts and metallic endoprosthetics. Further elucidation about individual procedures is essential, but beyond the scope of this chapter. Special considerations should also be recommended in a skeletally immature child, with long-term growth and functional outcomes in mind. With advances in imaging modalities, surgical techniques and engineering innovations, the necessity for amputation in an ES patient would arise in scarce minority (<5–8%) of cases. Pathological fracture and neurovascular involvement may make limb salvage difficult but are not absolute contraindications [65].

Patients receiving definitive RT as the only local therapy modality usually represent an inherently unfavorable group with either tumors in sites not amenable to surgery (e.g., vertebrae) or with large volumes (independent poor prognostic factor). Definitive RT should be recommended for tumors where organ and function preserving surgery is not feasible or would be associated with significant morbidity. It is also recommended for patients with tumors where only an intralesional resection is feasible. Such debulking surgeries result in inferior disease control and necessitates adjuvant RT and thus adding to treatment-related morbidity. Both Cooperative Ewing Sarcoma Study (CESS) and European Intergroup - CESS (EI-CESS) trials confirmed that local control rates were similar in patients with an intralesional resection followed by RT as compared to those with definitive RT [62]. The indications for postoperative radiotherapy include positive surgical margins, poor histologic response to chemotherapy, large soft tissue component, pretreatment pathological fracture and contamination of surrounding normal tissue due to inadequate surgery [66]. The comparison of outcomes of ES patients between the UK Children's Cancer and Leukaemia Group (CCLG) and German Pediatric Oncology and Hematology Group (including Austria, Switzerland and Netherlands) (GPOH) treated in EICESS-92 clinical trial showed a significant impact of the choice of local therapy modality (14% higher local recurrence rate in the CCLG group). The analysis underscored the preferential "over-use" of RT (preoperative or postoperative, as per the treating physician's discretion) in the GPOH group as a major contributor for the better outcomes. Also, this benefit was more significant in the group of patients given postoperative RT due to residual viable tumor >10% than in those whom postoperative RT was given due to marginal or intralesional resections [67].

The St. Jude's Children Research Hospital experience with lower than 40 Gy radiation dose showed higher local recurrence rates [68]. For definitive RT, the recommended dose is between 55 and 60 Gy. Higher doses of RT with conventional fractionation of 1.8–2.0 Gy/ fraction have been tried with encouraging results and the long-term outcomes are awaited. Hyperfractionated RT did not result in improved local control or significantly reduced toxicity. For postoperative RT, doses of 45–50 Gy respectively is recommended based on a negative or positive surgical resection margin. The Pediatric Oncology Group (POG) randomized trial (POG #8346), laid the basis for the concept of "Tailored Portals" for RT in ES. The radiation of the tumor and an additional safety margin sufficed for equivalent local control rates in this randomized trial with that of radiation to entire tumor bearing compartment, resulting in significant reduction in toxicity [69]. In cavitary lesions like pelvis and thorax, targeting the residual tumor volume post chemotherapy may be adequate. Modern RT techniques like 3-dimensional conformal radiation therapy (3D-CRT) and intensity-modulated radiation therapy (IMRT) have allowed significant sparing of normal tissues thereby reducing the possibilities of long-term adverse effects of RT. Technologies like proton beam therapy could further reduce adverse effects of RT and also allow RT dose escalation and improved local control.

8 Recurrent Ewing Sarcoma

Despite the insights gained and translated into the treatment of ES patients, around 20–30% of localized ES and 40–80% of metastatic ES patients will have recurrences. Early recurrences (within 2 years of initial diagnosis) and combined recurrences (local and metastatic) portend very poor further prognosis [70]. Although reports have suggested that local recurrence in ES almost always is followed by metastatic progression eventually [67]. ES shares the distinctive characteristic of other sarcomas, as opposed to other pediatric and adolescent tumors, that late and very late recurrences (up to 17.1 years after initial diagnosis) are also reported [71]. Hence, long-term continued monitoring and evaluations are recommended. The optimal modality of investigations for detection of recurrence is not supported by high level of evidence but a randomized trial of chest radiography versus CT scan of thorax and 3 monthly versus 6 monthly monitoring did not suggest an impact on survival after recurrence in bone malignancies [72].

Treatment after recurrence of ES is again multimodal with chemotherapy (topotecan, irinotecan, temozolomide, reuse of ifosfamide, cyclophosphamide and etoposide and sometimes with gemcitabine and docetaxel), surgical excision of all lesions, if feasible, and use of RT (definitive or adjuvant). The use of prolonged immunomodulatory metronomic maintenance therapy, has shown benefit in high-risk localized rhabdomyosarcoma in a recent report, may have a role in recurrent ES and is currently under investigation [73].

9 Ewing Sarcoma in the Adolescent and Young Adults (AYA)

The EI-CESS tumor registry showed that 56% of ES present in the second decade of life. Significantly more AYA ES presented with metastases, with larger tumor volumes and had poorer response to chemotherapy in this dataset [31]. The prognosis in the AYA ES patients has been historically shown to be poorer than in children. But more recent reports, when AYA ES patients under the age of 40 are treated with "pediatric like" aggressive protocols have abrogated these differences [56]. The factors that may impact the outcomes of AYA ES are described in Table 3.

ES could be considered a typical example of an AYA cancer, underlining the need for adaptation in understanding of unique biological and psychosocial distinctions and resultant requirements for this age group. The movements toward formation of a separate AYA Oncology Care Units in United Kingdom (Teenage Cancer Trust—www.teenagecancertrust.org), United States (Teen Cancer America—teencanceramerica.org) and Australia (CanTeen—www.canteen.org.au) are steps in the right direction for provision of specialized and optimal physical, medical, spiritual and psychologic space and care for AYA ES patients.

Table 3 Probable factors impacting outcomes of AYA ES

Type	Factors	Comments
Host-related factors		
	Growth spurts during adolescence	Possible implications on tumorigenesis and future therapies
	Hormonal changes during adolescence	Correlations not yet studied or adequately understood
	Comorbidities	Sports-related or physiological
	Pharmacokinetics	Decreased drug metabolism with increasing age as compared to children
	Pharmacodynamics	Increased toxicities with similar drug dose exposure (like peripheral neuropathy, cardiotoxicity)
	Compliance to treatment	Psychosocial impact on AYAs
	Adolescent behavior	Risk taking, ignoring symptoms, less amenable for referrals, peer pressures
Disease-related factors		
	More axial than appendicular location of tumors	Late presentations and less amenable to complete resections
	Larger volumes	Late presentations and requiring more intensive treatment modalities
	Different biology	Inherent chemotherapy resistance
Healthcare infrastructure-related factors		
	Lower enrollment in clinical trials	Less "disciplined" treatment compliance
	Treatment in inappropriate clinical setting	Adolescents being either treated in "pediatric" or "adult" units under respective protocols

Table 4 Potential long-term side effects in patients with ES

Group	Causative factors	Potential side effect	Comments
Cardiac	Doxorubicin Radiation to chest wall	Cardiomyopathy Early-onset metabolic syndrome	• Baseline and periodic cardiac function monitoring during treatment and later. • Limiting the dose of doxorubicin. • Using modulated radiation techniques and innovations. • Dexrazoxane administration. • Monitoring and correction with lifestyle modifications.
Gonadal	Alkylating agents Radiation	Sterility (predisposition in males)	• Adequate counseling at baseline. • Cryopreservation of sperms and ova (in post pubertal patients) before starting treatment. • Transposition of ovaries and testis (if in radiation field).
Musculoskeletal	Radiation Amputation Limb-sparing surgeries with prosthesis	Growth deficits Loss of limb and function Late prosthesis failure/ infections	• Consideration during planning of RT (see text). • Rehabilitation (physical, vocational and psychosocial). • Provision for continued follow-up and cost of continued care.
Second malignancies	Anthracyclines Alkylating agents Radiation	Acute leukemia Myelodysplasia Sarcoma in radiation field	• Limited scope for prevention. • Treatment as de-novo cancers.
Renal	Ifosfamide Cyclophosphamide Radiation to bladder/ kidneys	Renal tubular damage Bladder fibrosis	• Periodic relevant monitoring during treatment and prevention. • Bladder rehabilitation (if fibrosis).
Psychosocial	Adolescence Prolonged and intensive treatment Loss of limb/function Loss of educational/ vocational opportunities Peer pressures	Impact on treatment compliance and hence outcomes Loss of self-confidence Depression/anxiety	• Age-appropriate counseling before and during treatment and continued during follow-up. • Formation of social support groups for sarcoma survivors. • Creation of opportunities for educational / vocational rehabilitation for reintegration back into society as productive contributing members.

10 Long-Term Complications in Survivors of Ewing Sarcoma

Majority of patients with localized ES and substantial number of patients presenting even with metastases, will be cured of the disease and will be long-term survivors. The intensive treatment modalities used to achieve these cure rates may result in acute and late toxicities. Table 4 describes important considerations for prevention, monitoring and management of some of these long-term toxicities.

Optimization of appropriate treatment modalities used in the treatment of ES can help modulate (if not prevent) some of these potential long-term side effects and deserves adequate attention starting from initiation of treatment and continued during follow-up.

11 How We Do It at TMC

A suspected case of ES is advised a radiograph and MRI of the concerned region. A core needle biopsy establishes the diagnosis. PET-CT scan (including CT chest) is done for staging. Neo-Adjuvant chemotherapy (vincristine, ifosfamide, etoposide, cyclophosphamide and doxorubicin-based regimen) for 12–16 weeks is followed by local therapy. All patients after completion of neo-adjuvant chemotherapy are evaluated for feasibility of a surgical resection. For patients undergoing surgery, postoperative adjuvant radiation therapy is considered for positive/ close surgical margins or if histologic response is suboptimal, based on discussion in the multidisciplinary joint meeting. Patients with inoperable primary disease are considered for definitive RT. Adjuvant chemotherapy is continued as a maintenance for a total of 14–16 courses (dactinomycin replaces doxorubicin respecting cumulative dose limits).

Each decision point (planning of treatment, local therapy, palliation) is ideally discussed in multidisciplinary joint meeting. Financial, nutritional and psychosocial support is optimized based on need.

1 Introduction

Wilms tumor (nephroblastoma), an embryonal neoplasm, accounts for approximately 90% of all pediatric renal tumors. It rarely occurs in adolescent or adults, accounting for less than 1% of all renal tumors [1]. Multidisciplinary approach in the treatment of this cancer has evolved over the decades through cooperative group studies and has shaped the current treatment strategies with outstanding results. The two largest collaborative groups that have studied the optimal management of Wilms tumor are the Children's Oncology Group (COG) and the International Society of Paediatric Oncology (SIOP). Substantial progress has been made by refining risk stratification and application of molecular information that helps in tailoring treatment to maximize cure with minimal late effects.

2 Epidemiology

The incidence of Wilms tumor (WT) is 7.1 cases per 1 million children younger than 15 years. Approximately 650 cases of WT are diagnosed in the United States and 80 cases in the UK each year [2]. Asians have a lower incidence of WT. As per the National Cancer Registry program (NCRP) report of hospital-based cancer registries (2007–2011), the proportion of childhood cancers relative to cancers in all age groups in India varied between 1.2% and 10.5%. Of these, renal tumors comprised 1.8%–4.8% in boys and 2.4 %–5.9% in girls in different registries [3]. The tumor is usually unilateral, but synchronous bilateral or multifocal tumors can be seen in approximately 5%–10% of patients. The male to female ratio is 0.92:1 in unilateral cases and 0.6:1 in bilateral cases. The mean age at diagnosis is 44 months in unilateral and 31 months in bilateral cases [4, 5]. An associated congenital malformation syndrome in seen in around 10% of WT patients [6].

3 Embryology and Pathology

The definitive fetal kidney develops from the ureteric bud forming collecting ducts and blastema, which subsequently forms the stroma and the rest of the tubular structures. The blastema usually disappears by 36 weeks gestation but is retained in 1% of infants where they are called "nephrogenic rests" that can be induced to form WT through acquisition of genetic mutations or epimutations. In 40% of unilateral and 90% of bilateral WT patients, these nephrogenic rests can be identified [7]. Nephroblastomatosis is defined as the "diffuse or multifocal presence of nephrogenic rests or their recognised derivatives."

Histologically, there are three main types of cells in the tumor: blastema, epithelial, and stroma (mesenchyme) (Fig. 1a). Histopathology is used across cooperative groups to assess risk. In COG protocols, which advocate upfront surgery, presence of anaplasia (diffuse and focal) is a high-

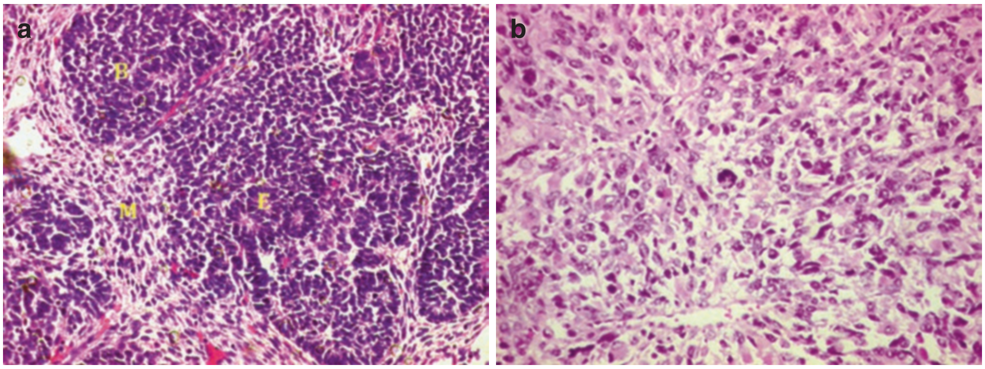

Fig. 1 (**a**) Triphasic Wilms tumor containing epithelial tubules (E), blastemal cells (B) and mesenchymal cells (M). Hematoxylin and eosin stain, 20×. (**b**) Microphotograph showing Wilms tumor with anaplasia. Enlarged, hyperchromatic nuclei are seen along with atypical mitotic figures. Haematoxylin and eosin stain, 20×

risk factor and in SIOP protocols, which recommend delayed surgery post neoadjuvant chemotherapy for 4–6 weeks, diffuse anaplasia and blastemal predominance is considered high risk and requires treatment modification. Anaplastic histology is seen in about 10% of WT and is considered the single most important histologic predictor of response and survival. The features of anaplasia include (a) hyperchromasia and (b) multipolar mitotic figures (Fig. 1b).

Any of the following situations on histopathology merits assignment to the "diffuse anaplasia" category:

1. Nonlocalized anaplastic change in the tumor specimen
2. Anaplastic change or nuclear unrest (nuclear or mitotic abnormalities that approach, but do not attain, the degree required for designation of anaplasia) in invasive sites or any extrarenal deposits
3. Localized anaplastic change in a tumor with severe nuclear unrest elsewhere
4. Anaplasia in a random biopsy specimen
5. Anaplasia involving the edge of one or more sections, and the site(s) from which the sections were taken cannot be determined.

If anaplasia is confined to one or more discrete areas, is not present in extrarenal sites, and cells outside of the anaplastic site show no features of nuclear unrest, it is considered "focal anaplasia."

4 Genetics and Epigenetics

Commonly mutated genes in WT are few, the discovery of which began with studying the constitutional predisposition syndromes of WT. Approximately one-third of WT cases involve mutations in WT1(11p13 locus), CTNNB1, or WTX [8]. A second WT gene; WT2 maps to 11p15 locus, and germline defects manifest as Beckwith–Wiedemann syndrome (BWS). BWS has different molecular mechanisms, and the overall tumor risk is between 5% and 10% [9]. Another 20% of WT cases results from mutations in miRNA processing genes (miRNAPG), including DROSHA, DGCR8, DICER1, and XPO5 [10]. Other recurrently mutated genes in WT include SIX1 and SIX2 (transcription factors that play key roles in early renal development) [10], EP300, CREBBP, and MYCN [11].

Table 1 Wilms tumor (WT) predisposition in genetic disorders

	Gene	Risk of developing WT
WAGR syndrome	WT1	50%
Denys-Drash syndrome	WT1	90%
Frasier syndrome	WT1	<5%
BWS—Overall risk	WT2	4.1%
• Loss of imprinting at ICR2	WT2	1–2%
• Gain of methylation at ICR1	WT2	22.8%
• Paternal 11p15 isodisomy	WT2	6.2%
Sporadic aniridia	WT1	50%
Isolated hemihyperplasia		5.9%

Around 30%–50% of mutations appear to converge on the process of transcriptional elongation in renal development and include the genes MLLT1, BCOR, MAP3K4, BRD7, and HDAC4 [11]. Anaplastic WT is characterized by the presence of TP53 mutations. The risk of developing WT in various genetic disorders is detailed in Table 1.

5 Clinical Presentation

Majority of patients present with an asymptomatic abdominal mass detected usually by the caregiver or by pediatrician during visit for unrelated reasons. Abdominal pain (mild in intensity, dull ache) is present in approximately 40% of children. Gross hematuria is observed in 18% of children (and 24% have microscopic hematuria). Hypertension, due to increased renin activity, is seen in about 25% of children which usually abates following nephrectomy [12]. Constitutional symptoms such as fever, anorexia, and weight loss are uncommon and seen in 10% of patients. Atypical presentations, seen in <10% of cases, are mostly due to vascular infiltration or compression of surrounding organs. These include vascular extension into renal vein or inferior vena cava, seen in 4% of patients which can present as hepatomegaly, limb edema, ascites, or even varicocele [12]. Occasionally, a child may present with acute abdomen with severe abdominal pain, tender mass, anemia, fever, and hemodynamic instability suggestive of tumor bleed or rupture, which may require emergency surgical intervention.

Acquired Von Willebrand syndrome (AVWS) type I or III is seen in about 1% to 8% of WT, due to complete absence of an inhibitor against VWF and responds to chemotherapy and/or tumor resection. Absorption of VWF multimers on to nephroblastoma cells resulting in a reduction of plasma levels of VWF [13] or hyaluronic acid produced by nephroblastoma cells may be the causative factor in atypical AVWS in WT, which may be associated with bleeding [12, 14, 15].

6 Evaluation and Workup

Baseline investigations to be done are as follows:

1. Physical examination should include
   (a) Blood pressure measurement
   (b) Nutritional status assessment
   (c) Examination of abdominal mass and liver
   (d) Looking for congenital anomalies and syndromic features especially overgrowth features, hemihypertrophy, aniridia, genitourinary anomalies, and any developmental delay
2. Complete hemogram
3. Biochemistry: liver and renal function tests
4. Coagulation tests, especially if AVWS is suspected
5. Ultrasound scan of abdomen: Done as an initial investigation to define the epicenter of the tumor, and it can also identify associated intravascular thrombus, liver metastasis, and associated genitourinary anomalies.
6. Contrast-enhanced CT scan of abdomen, pelvis, and chest: Confirms the renal origin of tumor, location in the kidney, size and laterality, presence of renal vein or IVC thrombus, abdominal lymphadenopathy, tumor rupture, infiltration of adjacent organs, and metastases to liver or lung (Fig. 2).

   In case of multifocal or diffuse lesions, MRI helps better to differentiate between tumorous lesions and nephroblastomatosis. They are usually homogenous with little contrast enhancement and retain the shape of the rests and so are lenticular in multifocal lesions or are seen as diffuse thickening.
7. In rare cases where intracardiac thrombus is detected, an echocardiogram should be done.
8. Fine-needle aspiration cytology/biopsy of the tumor: This may be done as per institutional practice and is not mandatory especially if upfront nephrectomy is contemplated. It should be considered in upfront inoperable cases to exclude non-WT cases and in unusual clinical presentations (older age, i.e., >5 years, urinary infection, sepsis, unusual radiological findings such as calcifications, voluminous adenopathies, renal parenchyma not visible, or totally extrarenal process). Needle biopsy should be by a retroperitoneal approach and image guided if possible.

Needle biopsy prior to preoperative chemotherapy is permitted but not considered standard practice according to the current SIOP protocol. Additionally, needle biopsy is not taken into account for staging purposes in SIOP protocols, which is solely determined based on nephrectomy specimen regardless of timing of the same. However, if a wedge or open biopsy is performed, the tumor gets upstaged to stage III. COG guidelines recommend upstaging to stage III if any biopsy (Trucut/needle or wedge) is done for diagnosis prior to starting therapy.

Biopsy is not required in bilateral renal tumors as diagnoses other than WT are very rare and biopsy rarely detects high-risk pathology such as anaplasia. Needle biopsy is contraindicated in children <6 months of age (where upfront surgery is advocated as chances of benign lesions like mesoblastic nephroma and non-WT lesions like rhabdoid tumor are high), and if there is suspicion of tumor rupture or bleed. Biopsy is also unlikely to benefit in pure cystic tumors where upfront surgery is recommended.

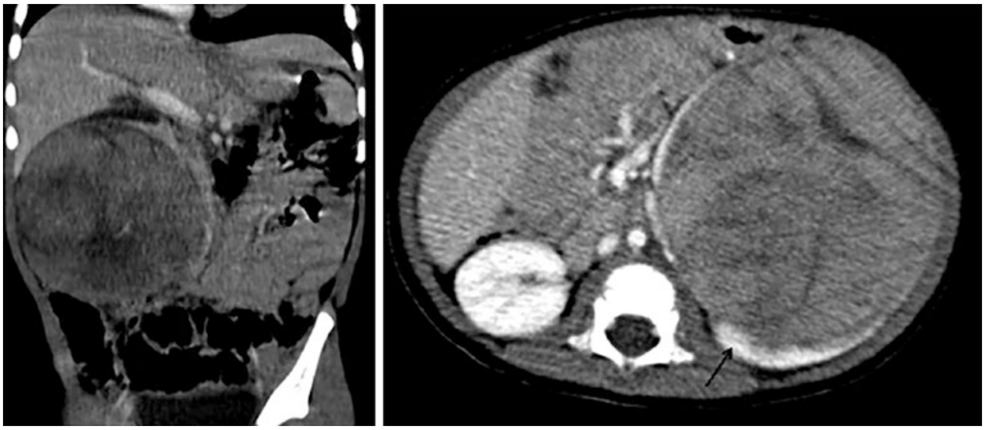

Fig. 2 Figure shows a well-defined lesion due to the formation of pseudocapsule with intrarenal origin indicated by the presence of 'claw' sign (shown by the black arrow on right side)

7 Principles of Management

The diagnosis and treatment of WT have evolved over the past decades though the collaborative efforts of the cooperative groups. The two largest collaborative groups that have contributed to the current treatment strategies are the COG (previous NWTS) and SIOP. A major difference in approach between the two groups is COG favors upfront surgery (nephrectomy), whereas SIOP favors preoperative chemotherapy followed by nephrectomy. There are several pros and cons highlighted for either of the two approaches as described in Table 2, but the outcomes have been comparable across both these approaches.

Histopathological assessment of tumor tissue helps in assessing risk type across both approaches though there are variations in same. Diffuse anaplasia is considered high risk across both groups. Risk categorization according to the groups is described in Table 3.

Table 2 Comparison between COG/NWTS and SIOP approaches to management of Wilms tumor

COG (Upfront Nephrectomy)	SIOP (Upfront Chemotherapy)
• Precise staging and pathology and, hence, accurate risk assessment • Fresh tissue available for molecular studies and research • Avoids unnecessary chemotherapy in case of benign lesions • Diagnosis of non-WT cases like rhabdoid tumor or clear cell sarcoma which warrants different chemotherapy is made early	• Reduces surgical complications like bleeding and tumor spillage • Decreases the use of doxorubicin and adjuvant radiotherapy by practically downstaging the tumor • Allows better surgical resection and reduces surgical morbidity • Renders an in vivo test of treatment response to NACT and tailors postoperative therapies, including identification of blastemal predominance, which requires high-risk therapy

Table 3 Risk categorization of Wilms tumor according to COG and SIOP

COG Classification (Upfront Surgery)	
Type	Histopathology Features
Favorable (FH)	No anaplasia
Unfavorable (UH)	Focal anaplasia Diffuse anaplasia
SIOP Classification (Upfront Chemotherapy)	
Risk	**Histopathology Features**
Low	Complete necrosis
Intermediate	Regressive (>66% necrosis) Epithelial predominant Stromal predominant Mixed type Focal anaplasia
High	Blastemal predominant (<66% necrosis with >2/3rd blastemal component) Diffuse anaplasia

7.1 Staging of Wilms Tumor

Staging is important in decision making, both for prognostication and therapeutic stratification of WT (Table 4). It is radiological- and surgico-pathological-based staging.

7.2 Treatment of Wilms Tumor

Wilms tumor treatment requires a multidisciplinary approach involving pediatric surgeon, pediatric radiation oncologist, pediatric oncologist, pathologist, and radiologist.

Table 4 Staging of Wilms tumor according to COG/NWTS and SIOP

Stage	Criteria
COG/NWTS Staging	
I	• Limited to kidney (without sinus vessel/capsule involvement) and completely resected AND • No tumor rupture AND No prior biopsy
II	• Extension beyond kidney but completely resected OR • Penetration of renal capsule OR • Invasion of renal sinus vessels
III	• Gross or microscopic residual tumor OR • Tumor spillage OR • Regional lymph node metastases OR • Positive peritoneal cytology OR • Transected tumor thrombus OR • Tumor rupture OR • Prior biopsy (wedge, FNAC or trucut)
IV	• Hematogenous metastases (lung, liver, bone, brain, etc.) OR • Lymph node metastases outside the abdomino-pelvic region
V	• Bilateral renal tumors at diagnosis
SIOP Staging	
I	• Limited to kidney (without sinus vessel/capsule involvement) and completely resected AND • No tumor rupture
II	• Extension beyond kidney but completely resected OR • Penetration of renal capsule OR • Invasion of renal sinus vessels/ vena cava but completely excised
III	• Gross or microscopic residual tumor OR • Tumor spillage OR • Regional lymph node metastases OR • Positive peritoneal cytology OR • Transected tumor thrombus OR • Tumor rupture OR • Tumor penetrating peritoneal surface/ tumor implant on peritoneal surface OR • Ureter transected OR • Tumor removed piecemeal OR • Wedge or open tumor biopsy prior to preoperative chemotherapy or surgery
IV	• Hematogenous metastases (lung, liver, bone, brain, etc.) OR • Lymph node metastases outside the abdomino-pelvic region
V	• Bilateral renal tumors at diagnosis

Historically, surgery alone was associated with 15%–20% 5-year survival across all stages that increased to 40%–50% with addition of radiotherapy. The introduction of chemotherapy improved survival to 60% with the addition of vincristine and dactinomycin which further increased to 70% with doxorubicin. The current survival rates of 90% are attributed to advances in surgery, pathology, radiology, and therapy. Integration of genetic and molecular information into risk stratification can further refine treatment, maximizing cure with minimal toxicity.

7.2.1 Surgery

Surgery remains mainstay in the treatment of WT though survival rates have improved with chemotherapy and radiotherapy. Radical nephrectomy with lymph node sampling via a transabdominal or thoracoabdominal incision, which allows thorough exploration of abdominal cavity, is the procedure of choice. Tumor removal should be complete and en bloc, without rupture because tumor spill has a sixfold increased risk of relapse [16].

Lymph nodes must be sampled and send for histopathological examination, even when not enlarged on clinical evaluation or radiology. This is required for accurate staging and subsequent treatment, as involvement of lymph nodes can lead to increased local recurrence and warrants administration of local radiotherapy [2, 12]. At least 5 LN stations are sampled including ineraortocaval LN to increase the likelihood of finding involvement [17]. These lymph node stations depends on the laterality of WT [18].

Renal-sparing surgery (partial nephrectomy or wedge resection) is recommended in children with bilateral WT, those predisposed to develop bilateral tumors (e.g., Denys-Drash or Frasier syndrome), and those with single/horseshoe kidney [19]. It is not recommended in standard unilateral tumors due to increased risk of tumor spill leading to recurrence and the relatively low risk of developing end-stage renal disease in long-term survivors of unilateral WT treated with nephrectomy [20].

COG advocates upfront surgery for WT, whereas SIOP advocates 4 and 6 weeks of chemotherapy for nonmetastatic and metastatic WT, respectively, with comparable survival outcomes, approaching 90% in localized and around 60%–70% in metastatic tumors at the population level. However, there are instances that may warrant preoperative chemotherapy in COG (bilateral WT, tumor thrombus in the inferior vena cava above the level of the hepatic veins, tumors invading surrounding organs with increased likelihood of surgical resection of vital organs, if surgical resection would result in excessive morbidity, or there is respiratory distress from extensive pulmonary metastases). Likewise, upfront surgery in SIOP is indicated in infants <6 months as benign causes like mesoblastic nephroma and non-WT causes like rhabdoid tumor are more likely and also when there is hemorrhage or tumor rupture with hemodynamic instability.

7.2.2 Chemotherapy

The three main drugs used in the treatment of WT are vincristine (VCR), dactinomycin (ACD), and doxorubicin (ADR) with cyclophosphamide, carboplatin, etoposide, and irinotecan added in high-risk cases with combinations varying as per protocol.

SIOP Approach: Preoperative Chemotherapy

As per SIOP protocol, two-drug (VCR+ACD) for nonmetastatic and three-drug (VCR+ACD+ADR) chemotherapy for metastatic WT patients are started soon after diagnosis. This preoperative chemotherapy is given for 4 weeks in case of nonmetastatic and 6 weeks in metastatic patients with reassessment for surgery done at 5th and 7th weeks, respectively.

Postoperative Chemotherapy

Post nephrectomy, the chemotherapy regimen is decided as per the risk stratification that takes into account staging and histopathology. The first dose of VCR following surgery should be given within 5–7 days of surgery, after assuring adequate bowel peristalsis, and no significant postoperative complications. Those who require radiotherapy should not have it delayed by >14 days post-surgery as delay can worsen outcomes. During radiation therapy, ACD and ADR are best avoided and can be given after a gap of 10–14 days in order to avoid excessive radiation toxicity. First subsequent dose of ACD after RT should be given at 50%. The postoperative chemotherapy is presented in Table 5.

Table 5 Postoperative chemotherapy [21–23]

Risk (histology-based)	Treatment		
	Stage I	Stage II	Stage III
Low risk	None	AV (27 weeks)	AV (27 weeks)
Intermediate risk[a]	AV (4 weeks)	AV (27 weeks)	AV (27 weeks) + flank RT[b]
High-risk blastemal predominant	AVD (27 weeks)	HR-1 (34 weeks)	HR-1 (34 weeks) + flank RT[b]
High-risk diffuse anaplasia	AVD (27 weeks)	HR-1 (34 weeks) + flank RT	HR-1 (34 weeks) + flank RT[b]

Abbreviations: A Actinomycin D, *D* Doxorubicin, *V* Vincristine, *HR-1* Etoposide, carboplatin, cyclophosphamide and doxorubicin

[a] Intermediate-risk, nonstromal, nonepithelial type with volume ≥ 500 mL was shown to have significantly improved outcomes when doxorubicin was added and hence in the SIOP-RTSG 2016 umbrella protocol same is advised [24]

[b] If there was diffuse tumor spill (outside of retroperitoneum),whole abdominal RT should be given

COG Approach: Adjuvant Chemotherapy

The COG protocol of chemotherapy for favorable histology WT, which risk stratifies based on staging, histology, molecular factors (LOH at 1p and 16q), after upfront radical nephrectomy, is shown in Table 6.

Table 6 COG protocol of chemotherapy for WT with favorable histology [25, 26]

Stage	LOH 1p & 16q	Risk Group	Treatment
Stage I <2 years, tumor ≤550 g	No	Very low risk	Nephrectomy and observation
Stage I	No	Low risk	EE4A—18 weeks
Stage I	Yes	Standard risk	DD4A—24 weeks
Stage II	No	Low risk	EE4A—18 weeks
Stage II	Yes	Standard risk	DD4A—24 weeks
Stage III	No	Standard risk	DD4A—24 weeks + RT
Stage III	Yes	High risk	Regimen M—31 weeks + RT
Stage IV lung (rapid responders)	No	Standard risk	DDR4—24 weeks + abdominal RT for local stage III, no lung bath
Stage IV	Yes	High risk	Regimen M—31 weeks + abdominal RT for local stage III + lung bath only for incomplete responders
Stage IV, non-lung metastases	No	High risk	Regimen M—31 weeks + abdominal RT for local stage III + RT to non lung metastases

EE4A, VCR + ACD; DD4A, VCR + ACD + ADR; Regimen M, VCR + ACD + ADR + Cyclophosphamide + etoposide

The protocol for unfavorable histology is more aggressive, with more intense chemotherapy and radiotherapy. It is depicted in Table 7.

Wilms Tumor with Pulmonary Metastases

Both the SIOP and COG protocols now are in agreement regarding radiotherapy in WT patients with pulmonary metastases in that if complete remission is attained, RT can be avoided though there is variation in the definition and scheduling of RT. The schema of approach to WT with pulmonary metastases is given in Fig. 3.

Table 7 COG protocol of chemotherapy for WT with unfavorable histology [23]

Stage	Focal Anaplasia	Diffuse Anaplasia
Stage I[a]	DD4A + RT	DD4A + RT
Stage II	DD4A + RT	Regimen UH-1 + RT[b]
Stage III	DD4A + RT	Regimen UH-1 + RT[b]
Stage IV	Regimen UH-1 + RT[b]	Regimen UH-2 + RT[b]

UH-1, VCR + ADR + cyclophosphamide + etoposide + carboplatin (revised UH-1 has lower cyclophosphamide dose); UH-2, VCR + ADR + cyclophosphamide + etoposide + carboplatin + irinotecan

[a] Stage I focal anaplasia on NWTS-5 was treated with two drugs (VCR + ACD) with lower outcomes compared to those who got 3 drugs (VCR + ACD + ADR) on retrospective analysis

[b] Stage II–III diffuse anaplasia and Stage IV focal anaplasia are currently given revised UH-1 chemotherapy to increase the outcomes on AREN0321 trial and if they have measurable disease post upfront surgery in stage IV diffuse anaplasia, they are offered UH-2

Fig. 3 The schema of approach to Wilms tumor with pulmonary metastases. FHWT, favorable histology Wilms tumor

Bilateral Wilms Tumor

Approximately 5% of all patients registered on NWTS-5 had bilateral WT [17] (Fig. 4). The risk of renal failure is a concern for patients with bilateral WT primarily secondary to loss of normal renal parenchyma due to bilateral nephrectomies (partial or complete) [12]. The incidence of end-stage renal disease is approximately 15% at 15 years post-surgery [19]. The challenge is the preservation of renal function mainly through nephron-sparing surgery (NSS), which complies with attainment of surgical resection with negative margins. Majority are too large at presentation for upfront NSS, and there are attendant surgical risks of intraoperative bleeding and postoperative small bowel obstruction. Therefore, preoperative chemotherapy is advocated to reduce tumor burden and facilitate NSS in this group [16]. These tumors have a significantly increased risk of anaplastic histology when compared to unilateral sporadic tumors; however, this is incongruent between kidneys and are mostly not picked up on initial biopsy if performed. Taking into account the above concerns in bilateral WT, management requires careful decision making with regard to chemotherapy, timing of surgery the type of surgery, and postoperative supportive care.

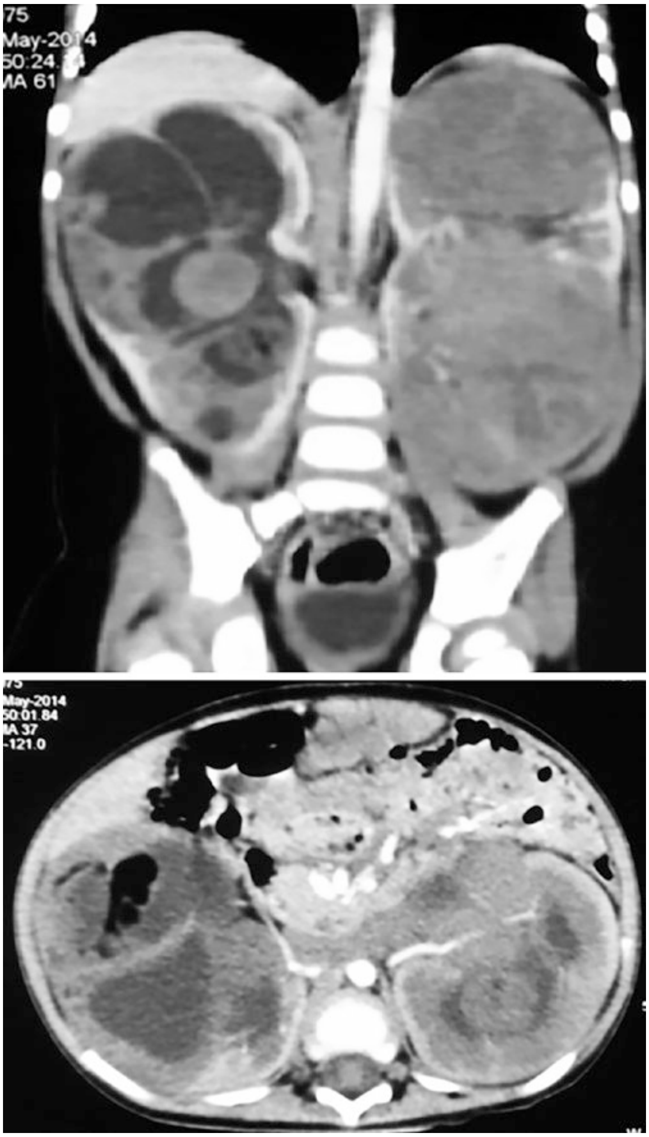

Fig. 4 Contrast-enhanced CT scan: coronal and axial images of bilateral Wilms tumor

There is current consensus between the COG and SIOP cooperative groups regarding the approach to bilateral WT. Upfront biopsy is not recommended if there are bilateral renal lesions. These children are given neo-adjuvant three-drug chemotherapy (VCR+ACD+ADR) and surgery done no later than 12 weeks, with first reassessment after 6 weeks. Review of data from St. Jude Children's Research Hospital showed that in bilateral WT, relapse was less when three-drug chemotherapy as described was used (8%) in comparison to two-drug preoperative chemotherapy (48%) [27]. The COG schema for bilateral WT (AREN0534) is presented in Fig. 5 [28].

Postoperative chemotherapy is based on histology using SIOP classification, as shown in Fig. 6.

Flank/abdominal radiotherapy is as per the local staging of WT. SIOP also initiates two-drug chemotherapy preoperatively for bilateral nonmetastatic WT (doxorubicin in metastatic and certain special cases for reinforcement) followed by surgery no later than 12 weeks and postoperative chemotherapy as per histology (described previously).

7.3 Radiotherapy

Radiotherapy should be started within 14 days of surgery unless there is a contraindication. COG and SIOP have different doses for various stages as depicted in Table 8.

7.4 Tackling Special Situations

7.4.1 Nephroblastomatosis

This can present unilaterally or bilaterally as multifocal or diffuse nephrogenic rests (NR) including the diffuse hyperplastic nephroblastomatosis with expansion of renal cortical tissue. The rests can be peri-lobar (PLNR), seen more in association with Beckwith-Wiedemann syndrome and hemihypertrophy or it can be intra-lobar (ILNR), seen more in the setting of WAGR and Denys-Drash syndrome [29]. SIOP recommends they be treated with two-drug chemotherapy (VCR+ACD) for a total duration of 1 year. Ultrasonography/MRI is used for assessing the lesions at the various time points. If WT develops at any time, multimodality treatment is given as per the stage, and two-drug regimen is continued for a total 1 year. Surgery has to be done if there is stabilization or progression of lesions in spite of chemotherapy, if a

nodular spherical lesion appears within the initial lesion or if the lesion becomes heterogeneous. Partial nephrectomy or wedge excision of the lesion should be done as in the case of bilateral WT.

7.4.2 Wilms Tumor with Tumor Thrombus

Preoperative chemotherapy with delayed surgical resection for intravascular thrombus is advocated by COG and SIOP. Upfront surgery is offered only for those patients with unstable thrombus likely to dislodge and cause acute symptoms (COG also does upfront nephrectomy for those with tumor thrombus in renal vein or infra-hepatic IVC). Although preoperative imaging usually delineates intravascular extension of the tumor, examination of the vena cava and renal vein should be done during surgery. A short renal vein thrombus may be resected along with the vein. Extension of thrombus to the infra-hepatic vena cava will require a vena cavotomy, after occluding the contralateral renal vein and cava above and below the thrombus. The thrombus should be removed and the venotomy closed. A longer thrombus (intra-hepatic, supra-hepatic, or right atrial) may require the assistance of a vascular or cardiac surgeon and cardiopulmonary by-pass. In cases with extensive caval wall infiltration, radiotherapy may be a better option as extensive surgery may not be able to achieve complete excision.

7.4.3 Inadequate Surgery

In developing countries, when upfront surgery of renal mass is done in peripheral hospitals, details are not available regarding tumor spill or lymph node sampling. The absence of node sampling may result in understaging and undertreatment of the tumor as reported by the NWTS group in 2005. Additionally, the pathological assessment of the tumor specimen is many a time inadequate leading to inappropriate risk stratification. Potentially, this could increase the risk of recurrence [2, 12]. An abstract presented in SIOP addresses

Table 8 Radiotherapy: indications and dose (COG and SIOP approach) [23]

Stage (COG)	Favorable Histology	Anaplastic Histology
I	No RT	10.8 Gy to tumor bed
II	No RT	10.8 Gy to tumor bed
III Tumor spill—localized —diffuse	10.8 Gy to tumor bed 10.8 Gy to flank 10.5 Gy to whole abdomen	19.8 Gy to tumor bed 19.8 Gy to flank 19.5 Gy to whole abdomen
IV	Local RT if Stage III + Address the metastases	Local RT if stage I-III + Address the metastases

Risk Group (SIOP)	**Treatment**		
	Stage I	**Stage II**	**Stage III**
Low risk	No RT	No RT	No RT
Intermediate risk	No RT	No RT	14.4 Gy(±10.8 Gy boost if residual)
High-risk blastemal predominant - Major rupture	No RT	No RT	25.2 Gy(±10.8 Gy boost if residual) 19.5 Gy
High-risk diffuse anaplasia —Major rupture	No RT	25.2 Gy	25.2 Gy(±10.8 Gy boost if residual) 19.5 Gy

RT to metastases:

Site	**Dose**
Liver—RT if lesions unresectable —If whole liver involved	25.2–39.6 Gy 19.8 Gy
Brain	Whole-brain RT to 21.6 Gy + boost of 10.8 Gy
Bone	25.2 Gy (Lesion + 3 cm margin)
Lymph node (if not surgically removed)	19.8 Gy

this very relevant issue in LMICs. In such cases, by giving three-drug chemotherapy in more than 100 patients, they have reported a 10-year DFS and OS of 84% and 89%, respectively, with acceptable toxicity [30]. So in such situations, three-drug chemotherapy with VCR+ACD+ADR without RT is a pragmatic approach.

7.4.4 Dosing in Infants

Initial NWTS studies showed that toxicity of chemotherapy was greater in infants [31]. Dosing based on body surface area (BSA) will deliver twice as much chemotherapy as dosing based on body weight. Also, metabolism of various drugs is immature in young infants. So chemotherapy should be weight based rather than BSA based. NWTS protocols recommend 50% dose reduction in infants [32].

7.4.5 Supportive Care

Hepatic Sinusoidal Obstruction Syndrome (SOS), Previously Known as Veno-occlusive Disease (VOD)

Child with SOS may present with abdominal pain, diarrhea, ascites, edema, tender hepatomegaly, and thrombocytopenia. The finding of portal hypertension or reversed portal venous flow on Doppler ultrasound is found only in advanced cases. The incidence was around 8% as defined by Seattle criteria in children treated under SIOP collaborative studies [33]. It typically develops after second to sixth dose of ACD, at 7–14 days after the last dose and resolves after a period of 6–180 days [33]. If SOS develops during preoperative chemotherapy, postoperative irradiation of large parts of the liver should be avoided. Acute episode should be managed with meticulous attention to fluid balance and restriction with diuretics when necessary. Patients with SOS should not be given ACD until the clinical findings and liver function normalize. During the first following course, patients should receive only 50% dose of ACD. If the symptoms reappear, this drug should be withdrawn permanently.

Cardiac Dysfunction

Children with WT on chemotherapy with doxorubicin should have echocardiography done at frequent intervals, after every 120 mg/m^2 of doxorubicin to detect any asymptomatic cardiac dysfunction. If ejection fraction is <50%, repeat echocardiography should be done prior to the next dose of doxorubicin and if normal to proceed with same. If it is still <50% or any time there is symptomatic cardiac dysfunction, doxorubicin should be withdrawn.

Hypertension

About 25% of children with WT have hypertension at presentation that can be treated with antihypertensives, especially angiotensin converting enzyme inhibitors. Calcium channel blockers may also be tried. Persistent hypertension usually responds to nephrectomy.

8 Molecular Prognostic Markers in Wilms Tumor

8.1 LOH 1p and 16q

NWTS-5 was prospectively designed to test the prognostic significance of LOH 1p and 16q across different stages of favorable histology WT [25], which showed that it was the most significant in prognostication after upfront surgery than either alone and was associated with a three-fold increased risk of relapse in Stage I/II tumors, which equated to relapse-free survival (RFS) of 75% versus 90% for those who had neither of these; for Stage III/IV, it was associated with a 2.5 times increased risk of relapse with RFS of 65% versus 83% for those with and without combined LOH 1p and 16q, respectively. The current AREN0532 and AREN0533 trials, which investigated intensifying therapy based on this, have shown improved outcomes. This molecular marker has not been found to be significant in studies that risk stratified based on post-chemotherapy histopathology as done in SIOP trials. However, combined LOH 1p and 16q is found only in 5% of newly diagnosed patients and <10% of relapsed cases.

8.2 1q Gain

Several studies have shown prognostic significance with respect to 1q gain across all stages in favorable histology WT. It is found in approximately 30% of newly diagnosed cases with a potential for risk stratification, influencing a significant proportion of patients and may be the driver mechanism in combined LOH 1p and 16q. In the COG study, which looked at the prognostic significance of 1q gain, the 8-year EFS and OS estimates were 77% and 88% for those with 1q gain and 90% and 96% for those without 1q gain [34], and in the presence of 1q gain, neither 1p and/or 16q loss was significant, though it retained significance in the absence of 1q gain.

8.3 TP53 Mutation

Diffuse anaplasia is recognized as high-risk histology across both COG and SIOP groups and is treated aggressively with chemotherapy and radiotherapy. However, recent analysis has identified TP53 mutations and/or 17 ploss in 62% of such cases and have found it to be associated with increased relapse and death when compared to those lacking TP53 abnormalities, which may further help to refine treatment in future [35].

8.4 11p15 Methylation

In AREN0532 studies, patients with very low risk WT (<2 years, stage I, FH, <550 g) with 11p15 LOH had an increased risk of relapse [AREN0532 Fall 2015 Final Study Progress Report].

9 Management of Relapse of Wilms Tumor

The two most important factors clearly associated with poor prognosis at relapse are anaplastic or SIOP high-risk histology and upfront doxorubicin use [36, 37]. They can be divided into the following [38]:

1. Standard-risk relapse (FH WT with prior VCR and/or ACD use)

   They benefit from doxorubicin, Etoposide and an alkylating agent (ifosfamide or cyclophosphamide) combined with radiotherapy.
2. High risk (FHWT with prior three or more drugs)

   The chemotherapy drugs commonly used are carboplatin, etoposide with either ifosfamide or cyclophosphamide. Topotecan has been added to the regimen to increase remission rates. High-dose chemotherapy with autologous stem cell rescue(ASCR) also may be tried. The studies seem to suggest a role for dose-intensive strategies to treat children with relapsing high-risk WT, although there is no consensus on whether or not high-dose chemo therapy with ASCR accounts for the improvement in post-relapse outcome compared with historical published data [38].
3. Very high risk (UHWT irrespective of prior chemotherapy)

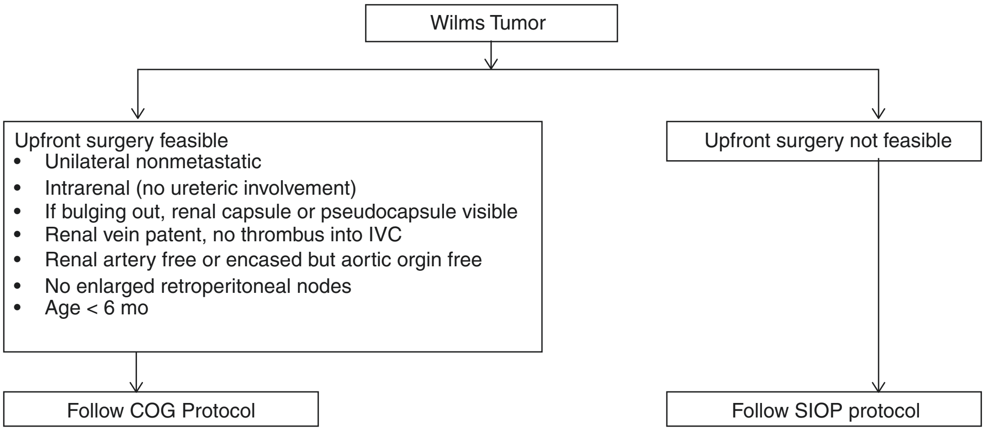
   They have poor outcomes post recurrence despite use of intense chemotherapy and needs novel agents.

Surgery in recurrent WT has not been examined prospectively, but seems to improve outcomes if complete resection is possible, especially after chemoreduction, though it cannot be excluded that they had less aggressive disease [38]. SIOP-RTSG 2016 guidelines include considering resection after proven reduction of relapsed disease after chemotherapy. Applying radiotherapy to initially nonirradiated sites is uniformly accepted, but for previously irradiated sites, it is better done after detailed discussion with radiation oncologists [24].

10 Treatment Algorithms Used in Tata Memorial Hospital

Step 1 (Fig. 7)
Step 2A (Fig. 8)
Step 2B (Fig. 9)

Fig. 7 Wilms tumor treatment: upfront surgery versus delayed surgery, Tata Memorial Centre Guidelines



Wilms Tumor
Upfront surgery feasible
Unilateral nonmetastatic
Intrarenal (no ureteric involvement)
If bulging out, renal capsule or pseudocapsule visible
Renal vein patent, no thrombus into IVC
Renal artery free or encased but aortic orgin free
No enlarged retroperitoneal nodes
Age < 6 mo
Upfront surgery not feasible
Follow COG Protocol
Follow SIOP protocol

Abbreviations

ACTH	Adrenocorticotropic hormone
ASCT	Autologous stem-cell transplantation
BuMel	Busulfan and melphalan
CEM	Carboplatin, etoposide and melphalan
CT	Computerized tomography
DFMO	Difluoro-methyl ornithine
EFS	Event-free survival
FISH	Fluorescence in situ hybridization
GM-CSF	Granulocyte-macrophage colony-stimulating factor
GTR	Gross total resection
HVA	Homo vanillic acid
MIBG	Metaiodobenzylguanidine
MIS	Minimal access surgery
MKI	Mitotic karyorrhectic index
MRI	Magnetic resonance imaging
OMS	Opsomyoclonus syndrome
PET	Positron emission tomography
SCT	Stem-cell transplant
USG	Ultrasonography
VIP	Vasoactive intestinal peptide
VMA	Vanillyl mandelic acid

1 Introduction

Neuroblastoma is the most common childhood tumor in the adrenal glands and sympathetic ganglia formed from the neural crest. Its inexplicable behavior, from spontaneous regression in infants to metastatic aggression in older children, has always been at the core of ongoing research. The clinical presentation depends on the site and the presence of metastatic disease seen in approximately half of the patients at presentation. Over the last decade, significant progress in molecular pathology, staging, risk stratification and therapy has occurred.

2 Incidence and Epidemiology in India and Global

Neuroblastoma accounts for 10% of pediatric cancers in high-income countries [1]. However, it accounts for only 1–3% of cases in low and middle-income countries [2]. The Indian Council of Medical Research (ICMR), National Cancer Registry Program, reported an incidence of neuroblastoma of 2.4–7.5% across India [3]. At the Tata Memorial Hospital (TMH), Mumbai, neuroblastoma constitutes 20% of all extracranial, extraosseous solid tumors in children below 15 years of age [4]. The median age of diagnosis is 19 months, and more than 90% are diagnosed before 5 years of age. Environmental factors like prenatal smoking, vaginal infection and occupational exposure to certain chemicals have been associated with neuroblastoma, but no conclusive evidence exists [5].

Owing to the absence of any known risk factors, efforts were made initially for the primary prevention of this disease by screening. The assumption of neuroblastoma at birth led to mass-scale screening in Japan and later in North America and Europe [6–8]. An increase in the incidence of early-stage neuroblastoma followed without a contemporaneous decrease in the incidence of advanced-stage disease in the screened children. Essentially biologically favorable disease

was identified by screening resulting in an overdiagnosing of some neuroblastoma that would have remained undiagnosed. The consequence included excessive diagnostic and therapeutic procedures with substantial psychological morbidity and mortality from therapy-related complications. Therefore, mass screening for neuroblastoma is not recommended [9, 10]. A familial predisposition is seen in 1–2%, and these children are diagnosed early at 9 months. They also tend to have multifocal or bilateral disease in about 20%. The siblings have a 6% risk of developing neuroblastoma [11]. Several germline mutations have been associated with familial neuroblastoma, including ALK gene mutations (75%), PHOX2B gene mutations and deletions at 1p36 or 11q14-23. Rarely, children with other cancer predisposition syndromes like neurofibromatosis type 1, Costello syndrome, Noonan syndrome, Li–Fraumeni syndrome and Beckwith–Wiedemann syndrome can be at increased risk of developing neuroblastoma [12].

3 Molecular Pathology

Based on clinical factors and biological features at diagnosis, children with neuroblastoma can be subdivided into a favorable and an unfavorable group [13].

- Low or intermediate-risk: These children are younger than 18 months and have a favorable prognosis, with survival rates exceeding 95%. These tumors frequently have gains of whole chromosomes and are hyperdiploid.
- High-risk: These children are older than 18 months and have an unfavorable prognosis, with less than 50% survival rates. They have metastatic disease, near diploid or near tetraploid, segmental chromosome abnormalities (gains or losses) and/or MYCN gene amplification.

The biological parameters that significantly influence overall outcomes include [14] the following:

Ploidy of Tumor Cell (DNA Content). Diploid DNA content significantly negatively impacts outcomes in children less than 18 months, while in older children, ploidy does not affect the outcomes.

Amplification of MYCN Oncogene. MYCN amplification is the first tumor-derived genetic marker with clinical and prognostic value. It is present in about 16–25% of cases of neuroblastoma and 40–50% of patients with high-risk neuroblastoma, show MYCN amplification [15]. It is strongly associated with rapid tumor progression and poor prognosis in patients of all ages with any stage of disease [16]. In addition, MYCN amplification is also linked with specific clinical and biological features. Adrenal primary tumors frequently are amplified than the primary thoracic tumors. There is a strong association between MYCN amplification and unfavorable histology, diploidy, high mitotic karyorrhectic index (MKI) and loss of heterozygosity at 1p. Although a four-fold copy increase using fluorescence in situ hybridization (FISH) is defined as MYCN amplification, a recent COG study showed a two- to four-fold increase (MYCN gain) associated with inferior outcomes compared to a less than two-fold increase in MYCN copy (wild type) [17].

Segmental Chromosomal Aberrations. Several segmental chromosomal alterations (SCA), including deletions of chromosomes 1p, 3p, 4p and 11q, and gains of chromosomes 1q, 2p and 17q, have been reported [18–21]. In children older than 12 months with unresectable neuroblastomas without metastases and infants with localized unresectable or metastatic neuroblastoma without MYCN gene amplification, SCA has a significant effect on event-free survival (EFS) and/or overall survival (OS) than children without SCA [20, 21]. SCA confers a higher risk of relapse and inferior outcome than numerical alterations. In an analysis of the INRG database, an SCA at chromosomes 1p, 11q and 17q noticed a higher risk of relapse and a poorer outcome in patients without MYCN gene amplification [19]. SCA is frequent in most high-risk tumors; however, its significance is not relevant. Recently, distal 6q losses and amplification of regions not encompassing the MYCN locus were associated with extremely low survival probability [22].

4 Clinical Presentation in India and Global

Neuroblastoma is a tumor of the sympathetic tissue; therefore, it can arise anywhere from the neck to the pelvis. Most neuroblastomas are seen in the abdomen, and the adrenal gland is the most frequent disease site. The symptoms vary as per the site of origin and could be an asymptomatic mass, symptoms due to the mass or metastatic disease or paraneoplastic symptoms. Large abdominal masses can cause bladder and bowel symptoms or impair venous return leading to bilateral lower limb edema (Fig. 1). Rarely renal vascular encasement and compression may lead to renin-mediated hypertension. Large thoracic tumors may cause mechanical obstruction and respiratory distress.

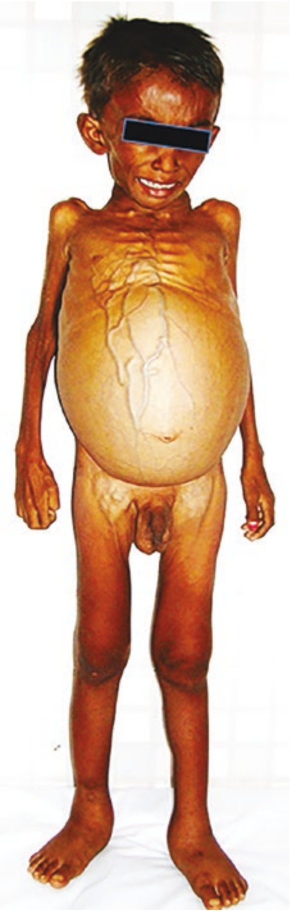

Fig. 1 Typical child with large abdominal neuroblastoma with dilated abdominal vein and bilateral pedal edema due to venous compression from the tumor mass. Extensive inguinal and cervical lymph node metastases is also present

Cervical and cervicothoracic lesions can produce Horner syndrome. Paraspinal tumors can extend into the neural foramina and may cause symptoms related to nerve roots and spinal cord compression. The metastatic disease typically presents as proptosis and periorbital ecchymoses (raccoon eye) due to tumor infiltration of the retrobulbar (Fig. 2). Extensive bone and bone marrow metastases cause bone pain, or pancytopenia leading to anemia, bleeding or infection. Massive liver metastasis, particularly in infants with stage 4S, may cause respiratory compromise, which could be fatal. Also seen in stage 4S disease is skin metastases presenting as bluish nontender subcutaneous nodules (mulberry nodule). Failure to thrive and fever may be seen with disseminated disease.

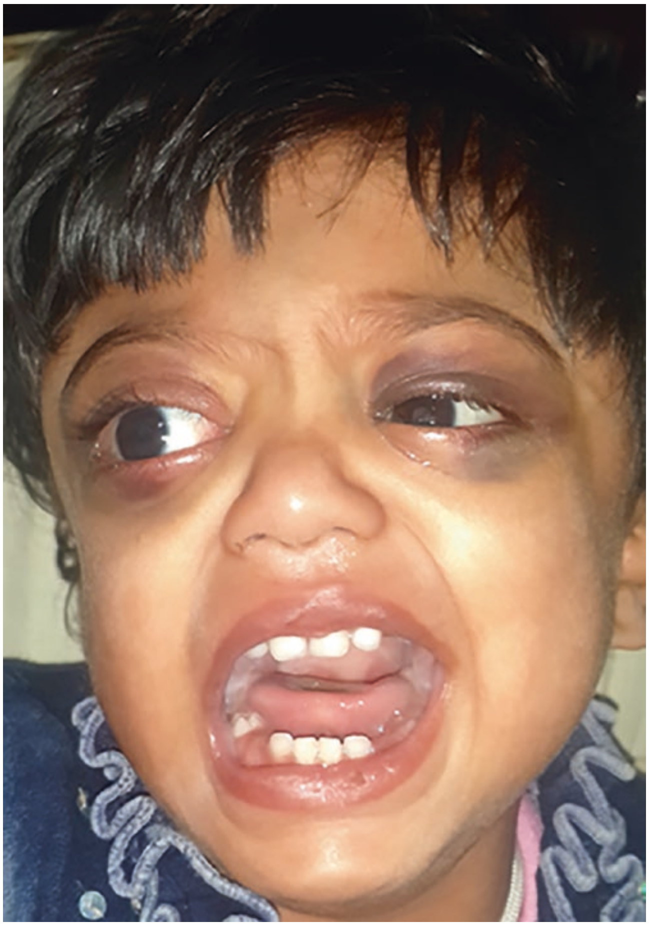

Fig. 2 Child with raccoon eye sign

5 Paraneoplastic Syndromes

Neuroblastoma is occasionally associated with paraneoplastic syndromes. Opsomyoclonus (Kinsbourne syndrome), a neurological paraneoplastic syndrome and diarrhea due to the vasoactive intestinal peptide (Kerner–Morrison syndrome), is a paraneoplastic hormonal syndrome associated with neuroblastoma.

5.1 Opsomyoclonus Syndrome (OMS)

Solomon and Chutorian gave the first association of this syndrome to neuroblastoma in 1968. It is seen in about 2–4% of newly diagnosed cases of neuroblastoma. The triad of opsoclonus (rapid and chaotic eye movements), myoclonus and ataxia and less frequent behavioral disturbances are noticed in these patients [23]. Pathogenesis seems to be an immunologic phenomenon wherein antibodies against neuroblastoma cells cross-react with neural cells in the cerebellum or elsewhere in the brain. Neuronal antibodies to Yo, Ri, Hu or amphiphysin may or may not be present, and antibodies can occur without a neurological syndrome. The treatment for OMS *per se* includes intravenous immunoglobulin, adrenocorticotropic hormone (ACTH) or corticosteroids, and Rituximab [24]. The underlying neuroblastoma in OMS is frequently associated with favorable biological features and has excellent survival rates [25]. Tumor resection certainly removes the antigenic stimulus and may improve the neurologic symptom, while chemotherapy could produce better results because of its immunosuppressive effects. Although likely with therapy, the neurological improvement may be a slow and partial or lifelong disability. Although the ideal Treatment varies, a combination of the different treatment approaches is undertaken. A randomized study of patients with OMS performed by the Children's Oncology Group (COG) showed an improved short-term neurologic response in patients treated with chemotherapy, corticosteroids and immunoglobulin, then without immunoglobulin [26].

5.2 VIP Syndrome (Kerner–Morrison Syndrome)

It is associated with increased vasoactive intestinal peptide (VIP) secretion, leading to watery diarrhea and hypokalemia. It is seen chiefly in mature tumors, and surgical excision usually leads to/results in the resolution of symptoms.

6 Evaluation and Work-Up

6.1 Tumor Markers

Urinary homo vanillic acid (HVA) and vanillyl mandelic acid (VMA) levels are raised in about 95% of neuroblastoma. They can be detected by either 24-hour urine collection or a spot urinary VMA level. These markers are additionally employed for monitoring response to therapy and surveillance for disease relapse following completion of Treatment [27].

Increased serum levels of ferritin and LDH signify disease burden. They have a potential for identifying a subgroup of high-risk patients with the poorest outcome, and this predictive strength can be exploited in low- and middle-income countries, where expert pathologic review may not be available, and resources may not exist to conduct genomic analysis of MYCN status and ploidy [28]. As a surrogate marker for identifying high-risk patients, the SIOP-PODC group has recommended serum ferritin ≥120 ng/mL and/or serum LDH ≥750 IU/L [29].

6.2 Bone Marrow Aspiration and Biopsy

Bilateral bone marrow aspirates and biopsies assess bone marrow to exclude bone marrow involvement. Immunohistochemical stains with neural-specific antibodies increase the sensitivity to at least 1 in 100,000 cells compared to 1 neuroblastic cell per 100 nucleated cells on light microscopy [30].

6.3 Radiology

Chest x-ray and ultrasound (USG) are routinely the initial investigations. Fine calcification may be seen in a plain x-ray of patients with large tumors. A contrast-enhanced computerized tomography (CT) scan is usually performed for all sites, while magnetic resonance imaging (MRI) is preferred for paraspinal disease with intraspinal extension (Fig. 3). The presence of specific features in radiology defined as image-defined risk factors (IDRF) is now used in the International Neuroblastoma Risk Group (INRG) Staging System for pretreatment risk stratification (Table 1). Twenty IDRFs have been identified based on the known locations of the primary tumor and the adjacent vital structures [31].

A skeletal survey for evaluation of bone metastases was performed previously; however, its utility is now restricted to confirming questionable bone metastases only. A technetium-99 bone scan is more sensitive for cortical bone metastasis.

Metaiodobenzylguanidine (MIBG) radionuclide scan is a precise and sensitive scan in neuroblastoma. It is the gold standard for diagnostic evaluation of neuroblastoma for both the primary tumor and sites of metastases [32]. Because ^{123}Iodine isotope is not available in India, ^{131}I-MIBG is used for diagnosis and therapy (Fig. 4). Semiquantitative scoring methods are available to evaluate the disease extent and assess response to Treatment which has prognostic value. The most common scoring methods are the Curie and the International Society of Paediatric Oncology Europe Neuroblastoma (SIOPEN). However, 10% of patients may have non-MIBG avid tumors [33]. Positron emission tomography (PET) with fluorine 18-fluorodeoxyglucose (see Fig. 4), though not as specific or sensitive as an MIBG scan, is preferred in patients with tumors that are not MIBG avid [34].

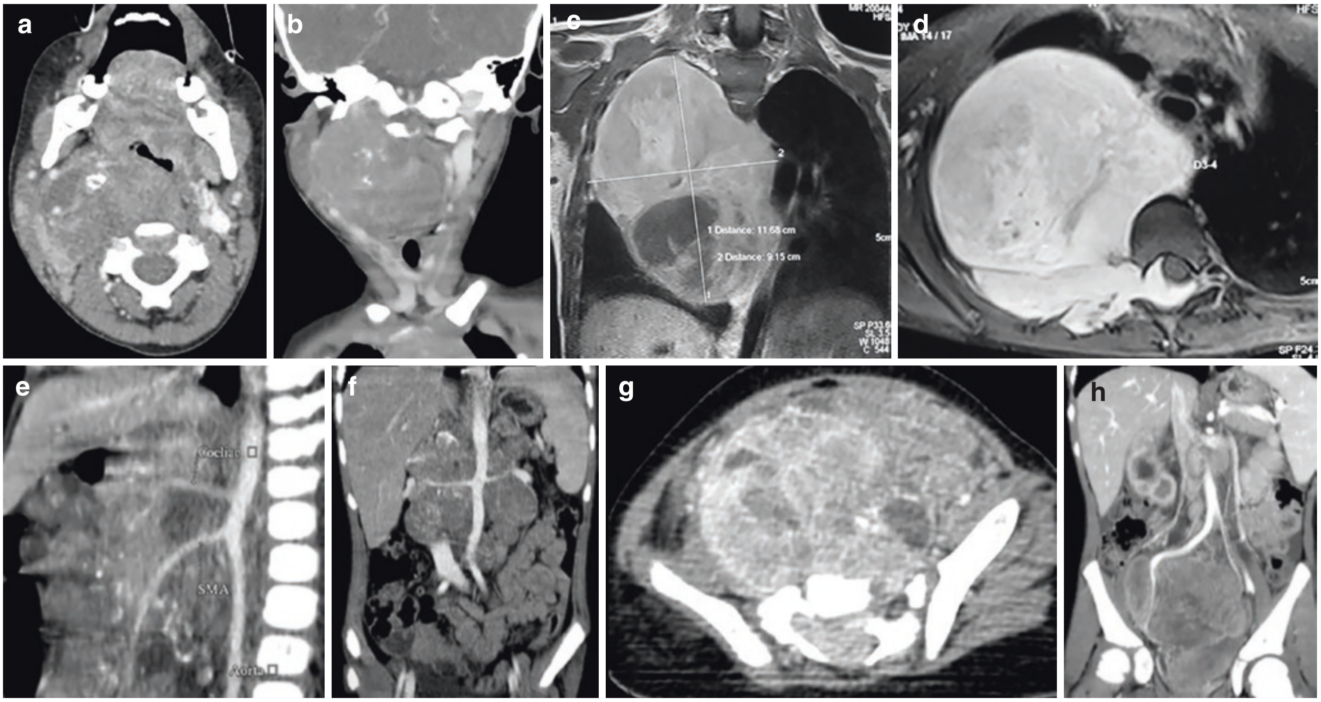

Fig. 3 Axial, coronal and sagittal computerized tomography images. (**a**, **b**) Cervical neuroblastoma with encasement of the carotid artery and compression of the airway. (**c**, **d**) Mediastinal neuroblastoma with more than one-third intraspinal extension. (**e**, **f**) Abdominal neuroblastoma with encasement of the coeliac, superior mesenteric and the renal arteries. (**g**, **h**) Pelvic neuroblastoma with intraspinal extension and encasement of the common iliac vessels

Table 1 Image-defined risk factors (IDRF) for neuroblastoma

Anatomic region	Description of IDRF
Multiple body compartments	Ipsilateral tumor extension within two body compartments (i.e., neck and chest, chest and abdomen or abdomen and pelvis)
Neck	Tumor encasing carotid artery, vertebral artery and/or internal jugular vein Tumor extending to skull base Tumor compressing trachea
Cervicothoracic junction	Tumor encasing brachial plexus roots Tumor encasing subclavian vessels, vertebral artery and/or carotid artery Tumor compressing trachea
Thorax	Tumor encasing aorta and/or major branches Tumor compressing trachea and/or principal bronchi Lower mediastinal tumor infiltrating costovertebral junction between T9 and T12 vertebral levels (because of risk of injury to anterior spinal artery)
Thoracoabdominal	Tumor encasing aorta and/or vena cava
Abdomen and pelvis	Tumor infiltrating porta hepatis and/or hepatoduodenal ligament Tumor encasing branches of superior mesenteric artery at mesenteric root Tumor encasing origin of celiac axis and/or origin of superior mesenteric artery Tumor invading one or both renal pedicles Tumor encasing aorta and/or vena cava Tumor encasing iliac vessels Pelvic tumor crossing sciatic notch
Intraspinal tumor extension	Intraspinal tumor extension (whatever the location) provided that more than one-third of spinal canal in axial plane is invaded, the perimedullary leptomeningeal spaces are not visible, or the spinal cord signal intensity is abnormal
Infiltration of adjacent organs and structures	Pericardium, diaphragm, kidney, liver, duodenopancreatic block and mesentery

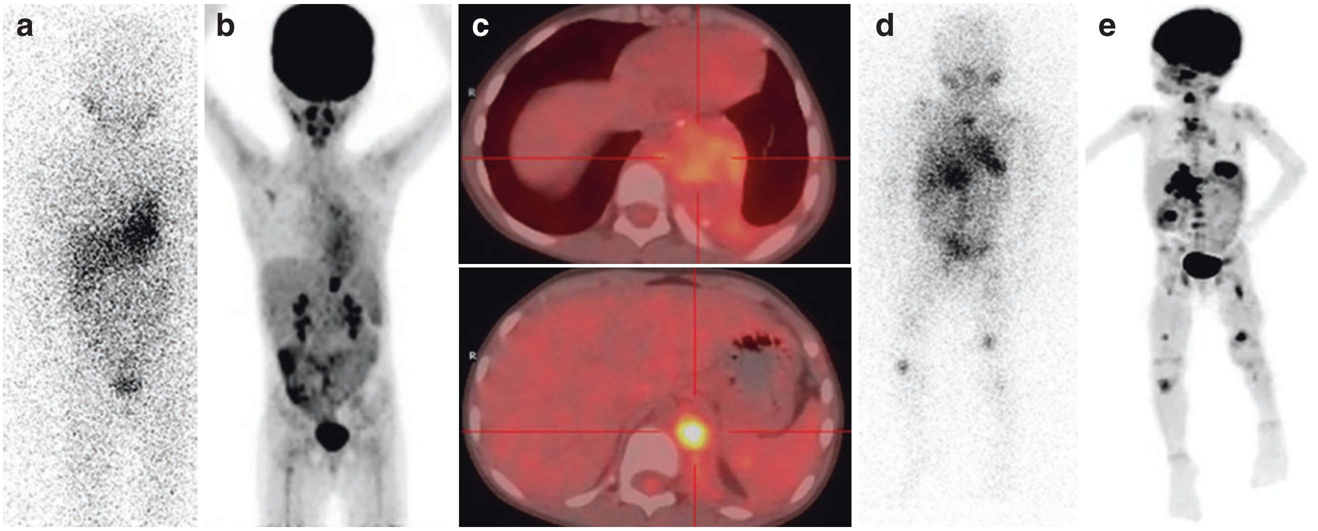

Fig. 4 ^{131}I-MIBG scintigraphy (**a**–**d**). Localized thoracoabdominal disease (**a**) and abdominal disease with skeletal metastases (**d**). Fluorine F 18-fluorodeoxyglucose-positron emission tomography scan (**b**, **c**, **e**). Same patients with localized (**b**, **c**) and disseminated (**e**) disease

6.4 Pathology

Neuroblastoma is a small round blue cell tumor of childhood with pathological features ranging from mature ganglioneuroma to less mature ganglioneuroblastoma to immature neuroblastoma with varying malignant potential. Histologically neuroblasts are small round cells with hyperchromatic nuclei almost filling up the entire cell. The neuritic process or neuropil is seen in most primitive neuroblasts. Homer-Wright pseudorosettes consisting of blue neuroblasts surrounding a central core of eosinophilic neuropil are also seen. Ganglioneuroma is composed of ganglion cells and Schwannian stroma, while ganglioneuroblastoma has features of both neuroblastoma and ganglioneuroma in varying proportions. Shimada et al. classified tumors as either favorable or unfavorable based on the patient's age and pathological features, including the presence or absence of Schwannian stroma, the degree of differentiation and the MKI [35].

6.5 Referrals Including Genetic Counseling

A family history of neuroblastoma, clinical features associated with mutations in predisposing genes, or elements suggesting predisposition such as bilateral or multifocal primary tumors qualify for genetic testing for mutations in neuroblastoma predisposition genes [36]. Surveillance with abdominal USG, urinary VMA and a chest radiograph should begin at birth or diagnosis of neuroblastoma predisposition and be continued every 3 months until 6 years of age, and then continued every 6 months until 10 years of age [36].

7 Staging

The International Neuroblastoma Staging System (INSS) staging for neuroblastoma was first described in 1986 and was a surgical staging system used by COG (Table 2) [37]. It could not be uniformly utilized on a larger platform for a clinical trial because it was all based on the surgeon's perception about the extent of resection. An alternative approach for presurgical staging based on clinical and biological features of the tumor and imaging was developed by the INRG task force in 2005. This has led to an INRG classification system and an INRG staging system [14, 38]. INRG has four subsets based on the presence and absence of IDRFs and metastatic status as LI, L2, M and MS. INRG stage MS is primary of any size/IDRFs with metastasis to liver, bone marrow or skin in children younger than 18 months (Tables 3 and 4 [14]).

Table 2 The International Neuroblastoma Staging System (INSS)

Stage/prognostic group	Description
Stage 1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (i.e., nodes attached to and removed with the primary tumor may be positive).
Stage 2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
Stage 2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically.
Stage 3	Unresectable unilateral tumor infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement. The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.
Stage 4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin and/or other organs, except as defined for stage 4S.
Stage 4S	Localized primary tumor, as defined for stage 1, 2A or 2B, with dissemination limited to skin, liver and/or bone marrow (by definition limited to infants younger than 12 months). Marrow involvement should be minimal (i.e., <10% of total nucleated cells identified as malignant by bone biopsy or by bone marrow aspirate). More extensive bone marrow involvement would be considered stage 4 disease. The results of the MIBG scan, if performed, should be negative for disease in the bone marrow.

Table 3 International neuroblastoma risk group staging system

Stage	Description
L1	Localized tumor not involving vital structures as defined by the list of IDRFs and confined to one body compartment.
L2	Locoregional tumor with presence of one or more IDRFs.
M	Distant metastatic disease (except stage MS).
MS	Metastatic disease in children younger than 18 months with metastases confined to skin, liver and/or bone marrow. The primary tumor can be INSS stage 1, 2 or 3.

IDRFs Image-defined risk factors

Table 4 International Neuroblastoma Risk Group (INRG) pretreatment classification [14]

INRG stage	Age (months)	Histologic category	Grade of tumor differentiation	MYCN	11q aberration	Ploidy	Pretreatment risk group
L1/L2		GN maturing, GNB intermixed					A (very low)
L1		Any, except GN maturing or GNB intermixed		NA			B (very low)
				Amplified			K (high)
L2	<18	Any, except GN maturing or GNB intermixed		NA	No		D (low)
					Yes		G (intermediate)
	≥18	GNB nodular neuroblastoma	Differentiating	NA	No		E (low)
					Yes		H (intermediate)
			Poorly differentiated or undifferentiated	NA			H (intermediate)
				Amplified			N (high)
M	<18			NA		Hyperdiploid	F (low)
	<12			NA		Diploid	I (intermediate)
	12 to <18			NA		Diploid	J (intermediate)
	<18			Amplified			O (high)
	≥18						P (high)
MS	<18			NA	No		C (very low)
					Yes		Q (high)
				Amplified			R (high)

GN Ganglioneuroma, *GNB* Ganglioneuroblastoma, *NA* Not amplified

8 Principles of Management

Neuroblastoma treatment includes observation or resection alone, restricted or substantial use of high-dose chemotherapy, including myeloablative therapy and stem-cell transplant (SCT), radiotherapy, isotretinoin and immunotherapy [39]. This wide availability of treatment options mandates a mechanism to identify patients who require no or high-intensity treatment. The tumor has been classified as low, intermediate or high risk in the earlier COG studies based on the INSS stage, age, International Neuroblastoma Pathologic Classification (INPC), ploidy, amplification of the MYCN oncogene, unbalanced 11q loss of heterozygosity and loss of heterozygosity for chromosome 1p [40]. With the introduction of the INRG classification system, the tumor has been classified as very low, low, intermediate or high risk based on INRG stage, age, histologic category, grade of tumor differentiation, MYCN amplification, 11q aberration and ploidy [14].

9 Surgical Management

Surgery plays a pivotal role in neuroblastoma treatment to accomplish local control of the disease. Due to the inherent tendency of these tumors for vascular encasement, resection can be a technical challenge [41]. The recognition of IDRF offers an actual appraisal of the complexity and the risk of surgical complications. Incomplete resection or surgical complications are typically seen in the presence of IDRF [42]. With due consideration to the IDRF, surgery can be considered in patients with L1 disease at presentation if necessary. All patients with L2 disease, especially high-risk diseases, should be considered for delayed surgery after chemotherapy. Irrespective of the primary disease site, adequate exposure for the surgical excision is paramount. This may range from minimal access surgery (MIS) to open exploration of two body compartments like a thoracoabdominal or cervicothoracic approach [43, 44]. Although very popular in general pediatric surgery, MIS is not always suitable for most neuroblastoma patients/presentations considering the complex relation to the vessels. However, for the small L1 disease, it may be appropriate in experienced hands, and MIS can even be utilized for obtaining biopsies. Complex sites like the cervicothoracic region require a cervicomanubriosternal approach or trapdoor approach [44]. The aim of surgery is complete safe surgical excision without sacrificing vital structures. However, this may not be feasible for most patients. Meticulous and persevering dissection safeguarding critical structures typically results in achieving the goal of safe resection [43]. The extent of surgery and the terminologies used to describe it are not uniform. Systemic failure in high-risk tumor neuroblastoma has prevented many from performing aggressive local surgeries; at the same time, extensive or unwanted surgeries have also been performed for low-risk diseases and tumors with intraspinal extensions. Complete resection with the removal of all visible and palpable macroscopic disease is usually called gross total resection (GTR). Incomplete resections have been variably defined as >95%, >90%, subtotal resections, etc., often on the intuitive assessment of the surgeon. Surgical complication rates have ranged from 5% to 25%. The frequent complications include vascular injury, prolonged intensive care stay, hemorrhage, nephrectomy, chylous leaks and neurologic deficits such as Horner syndrome and postoperative adhesions [44–46].

10 Medical Management

Essentially chemotherapy for neuroblastoma includes multiple rotating combinations of two or three drugs. The most common drugs used in various regimes include vincristine, etoposide, cisplatin, carboplatin, doxorubicin, cyclophosphamide, ifosfamide and topotecan [39]. Chemotherapy usually commences with multiple cycles as induction treatment with the primary purpose of reducing tumor burden, eliminating metastatic deposits if present, and rendering the tumor more amenable to surgical resection. Myeloablative therapy with carboplatin, etoposide and melphalan (CEM) regimen or busulfan and melphalan (BuMel) and autologous stem-cell transplantation (ASCT) is usually utilized for high-risk diseases [39]. Oral differentiation agent isotretinoin reduces the proliferation of neuroblastoma cells and induces differentiation after ASCT. Anti GD2 monoclonal antibodies after myeloablative therapy have improved the outcomes.

11 Radiation Management

The role of radiation has been limited due to various randomized trials, and its effect is variable in neuroblastoma. However, radiotherapy to the preoperative tumor bed after delayed surgical resection and ASCT is currently accepted as standard care for high-risk neuroblastoma. Radiotherapy is additionally used for spinal cord compression where chemotherapy does not improve symptomatically or in stage 4S, where enlarged liver with multiple metastases increases the abdominal pressure, and respiratory or renal compromise occurs. In the former, damage to the vertebrae may lead to scoliosis later in life. The use in unresectable or incompletely resected disease is not recommended currently. In the stage 4 disease with cortical bone metastasis, palliative doses for pain relief are given.

12 Metaiodobenzylguanidine (MIBG) Therapy

MIBG is an analog of the neurotransmitter norepinephrine. In their radioiodinated form, ^{131}I-MIBG and ^{123}I-MIBG are clinically used as tumor-targeted radiopharmaceuticals in diagnosing and treating neuroblastic tumors. ^{131}I-MIBG has a longer half-life than ^{123}I-MIBG, therefore, preferred in therapy. However, with variable results, MIBG therapy has been used only for refractory and relapsed neuroblastoma. For newly diagnosed high-risk neuroblastoma MIBG, Treatment is undergoing evaluation for use during induction therapy.

13 Risk-Wise Management Algorithms

13.1 Low-Risk Neuroblastoma

Observation or resection, chemotherapy restricted to symptomatic patients with low-risk biology can be offered for low-risk tumors [47]. Although surgery is preferred for L1 disease, observation alone is appropriate for asymptomatic infants with tumor volume less than 16 mL, even without a biopsy confirmation of the diagnosis [48]. After biopsy confirmation of favorable histology and MYCN nonamplification, other asymptomatic patients can also be offered a trial of observation [47–49]. Symptomatic patients can be provided limited chemotherapy to decrease tumor burden followed by a safe resection, preferably a gross total resection; however, even incomplete resection is acceptable for low-risk tumors [47]. Asymptomatic and favorable biology (MYCN nonamplified, no 11q aberration and hyperdiploid) stage 4S patients can also be observed given the excellent survival and spontaneous regression seen in 80% [47, 50]. Stage 4S patients with life-threatening symptoms frequently require intervention for multiple liver metastases causing hepatomegaly and raised abdominal pressure leading to respiratory compromise. Low-dose radiation (4.5–6 Gy in 3–4 fractions) to the liver or chemotherapy is used; the mortality rate remains high in this age group [51]. Surgical decompression was performed historically but had an increased risk of infection.

13.2 Intermediate-Risk Neuroblastoma

Mild- to moderate-dose chemotherapy is used for intermediate-risk disease, comprising carboplatin, etoposide, cyclophosphamide and doxorubicin, followed by surgery [52]. The number of cycles can be tailored based on the favorable and unfavorable features. The extent of resection has no impact on overall survival, as seen in both CCG and SIOPEN studies, including the experience in our institute [45, 53, 54]. In COG A3961, the favorable and unfavorable groups received chemotherapy comprising 4 and 8 cycles, respectively, and the 3-year EFS and OS were 88% and 96%, respectively. Radiation may be needed for progressive disease or unresectable disease during or after Treatment with chemotherapy [39, 52].

13.3 High-Risk Neuroblastoma

The Treatment of high-risk neuroblastoma generally has three phases: induction therapy, consolidation therapy and maintenance therapy [39]. The induction phase includes chemotherapy and surgical excision. The induction starts with multiple cycles of dose-intensive chemotherapy, including a platinum drug, anthracycline and alkylating agents. Response to therapy at the end of induction chemotherapy is followed by removal of the primary tumor. At the same time, progressive disease is either considered for other chemotherapy (irinotecan/topotecan, temozolomide) and reassessment or best supportive care. The advantage of a gross-total resection over incomplete resection is debatable; however, a safe, complete excision is usually the goal of surgery [55–57]. The consolidation phase involves myeloablative chemotherapy with ASCT (harvested during induction chemotherapy) to repopulate the bone marrow [58–60].

The maintenance therapy is aimed at treating the minimal residual disease after SCT. It includes radiation therapy to the primary site and areas of incompletely resolved metastases, retinoids and anti-GD2 antibody immunotherapy. The retinoids, isotretinoin and the new synthetic retinoid, fenretinide, induce cellular differentiation and slow the growth of neuroblastoma cells. GD2, a disialoganglioside expressed on neuroblastoma cells, is targeted with a chimeric monoclonal antibody known as dinutuximab, along with granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin-2 (IL-2) [61–63]. However, significant side effects, including severe pain as GD2, are found on peripheral pain fibers, fever, anaphylaxis with respiratory distress and hypotension. Newer approaches, including difluoromethyl ornithine (DFMO), an ornithine decarboxylase inhibitor, NK cells and CAR-T cells, are being studied katy, [64].

14 Risk-Wise Prognoses with Current Treatment

14.1 Low-Risk Neuroblastoma

Several studies have reported EFS exceeding 90% and OS ranging from 99% to 100% for low-risk diseases [47–49]. The COG-ANBL00P2 study reported 3-year EFS (for a neuroblastoma event) and OS of 97.7% and 100% for expectant observation even without a biopsy in infants under 6 months of age [48]. The COG has now initiated studies (ANBL1232) expanding the criteria for observation without surgery in infants up to 18 months.

14.2 Intermediate-Risk Neuroblastoma

The 3-year OS and EFS rate for intermediate-risk patients was 88% and 95% in the COG A3961 study [52]. In the subsequent COG ANBL0531 study, chemotherapy's duration and intensity were decreased to diminish side effects further. This study had a similar 3-year EFS of 83% and an OS of 95% [65].

14.3 High-Risk Neuroblastoma

The seminal Children's Cancer Group (CCG) phase III cooperative group study with myeloablative chemotherapy with ASCT had a significantly better 3-year EFS (34%) compared to nonmyeloablative chemotherapy (22%) without significant difference in OS (43% vs. 44%) [58]. The benefit in EFS and no change in OS remained on a reanalysis after a longer follow-up [66]. Similar results were observed in a Cochrane review evaluating myeloablative and SCT in a cohort of 739 high-risk patients [67]. The utility of dinutuximab along with GM-CSF and IL-2 in conjunction with isotretinoin over isotretinoin alone was confirmed in a COG phase III trial, which resulted in immunotherapy post-SCT as the standard of care for high-risk disease [61]. The recent randomized COG A3973 study showed better EFS (38%) and OS (50%) were reported compared to the previous studies [68]. The most recent COG-ANBL0532 study had a 3-year EFS of 51.1% and significantly better EFS for tandem transplants (62%) for single SCT (48%) [60].

15 Management of Recurrent Neuroblastoma

Recurrence in patients with high-risk disease carries a dismal prognosis [69]; however, recurrences in patients with low-risk and intermediate-risk neuroblastoma can be salvaged in most patients with observation alone, surgery alone or with moderate-dose chemotherapy, without myeloablative therapy and SCT [47, 52]. Treatment options for recurrent or refractory high-risk patients include chemotherapy (temozolomide, irinotecan/topotecan) combined with immunotherapy.^{131}I-MIBG alone or in combination with other therapy, ALK inhibitors, Crizotinib or lorlatinib for patients with ALK mutations.

16 Summary

- Significant progress has been achieved in the Treatment of patients with neuroblastoma.
- Neuroblastoma is the most common extracranial solid tumor in children.
- Presentation and disease course can be widely variable, ranging from tumors that display spontaneous regression or differentiate into benign variants to those that progress relentlessly despite Treatment and prove fatal.
- More than one-half of patients have widespread metastases at diagnosis.
- Age, stage and amplification of N-myc are important prognostic factors.
- Stratification of patients according to risk guides treatment.
- High-risk, refractory or relapsed tumors remain a clinical challenge.
- Reduction in cytotoxic therapies has been successful in children with low- and intermediate-risk diseases.
- Despite multimodal therapy, the outcomes for patients with high-risk neuroblastoma are suboptimal.
- Continued genomic and biologic characterization advancements will further enhance the identification of tumor-specific targets with therapeutic promise.

1 Introduction

Retinoblastoma (RB) is the most common malignant intraocular neoplasm in children [1]. Although long-term survival has improved to well over 90% with multimodality therapy in the developed world, it still causes fatalities in the low- and middle-income countries (LMICs) because of delayed presentation and treatment abandonment [2]. The management of RB has evolved over the past few decades and brought about a paradigm change from enucleation being the primary modality of therapy to a more multimodality treatment with an increased focus on globe preservation. The aim of RB therapy is not only to preserve life and eye but also to optimize residual vision and lately to focus on decreasing second malignancies. Early diagnosis of RB with the disease contained within the eye is key to better survival.

2 Incidence and Epidemiology

Retinoblastoma constitutes 2.5%–4% of all pediatric cancers with 11% occurring in less than 1 year of age [3]. About 8000 children worldwide are diagnosed with RB each year with an estimated incidence in India being 1200 cases annually. The age-adjusted incidence rates of RB in developed countries are 2–5 per million children (approximately 1:15,000 to 1:20,000 live births) [4] where RB is diagnosed early, in the intraocular stage, in 90% of cases with the median age of diagnosis of unilateral and bilateral RB at 24 months and 13 months, respectively [5]. In India, as in many other LMICs, the median age of diagnosis of unilateral and bilateral RB is 30 and 24 months, respectively, and only 60% of RB is diagnosed in the intra-ocular stage, with one-third presenting as locally advanced or metastatic disease [6]. Thus, India has a major burden of RB and the delay in diagnosis attributed to socio-economic barriers, leading to a large proportion of advanced disease presentations, which result in poorer outcomes [7–9].

3 Biology of Retinoblastoma

Retinoblastoma is the first tumor where a genetic origin was identified [10]. Knudson proposed the "two-hit hypothesis" in 1971, though the Rb1 gene was discovered later in 1986. According to Knudson's two-hit hypothesis, mutation in the 2 alleles of Rb1 gene results in the development of RB in children [11]. The Rb1 gene on chromosome 13q14.2 is composed of 27 exons that encode for 110kD nuclear phosphoprotein (pRb) [12]. Rb1, a tumor suppressor gene, is a regulator at the cell cycle checkpoint between G1 and entry into S phase [13]. In the heritable form, the first hit on the Rb1 allele occurs in the germ cell (germline mutation),

which affects every cell in the body, and the second hit occurs in the Rb1 allele of the retinal precursor cell during retinal development (somatic mutation). The hereditary RB also predisposes patients to second cancers like osteosarcoma, soft tissue sarcoma, and pineoblastoma (trilateral RB) [14]. The germline mutation of the Rb1 gene in the heritable RB is inherited from a carrier in 25% cases and the rest of 75% cases it occurs as a "de novo" mutation early in embryogenesis. In the "sporadic" nonheritable form, the two hits occur in the retinal precursor cell (somatic mutations) and the mutation is confined only to the retinal cells [15]. Additional genetic events predisposing to RB transformation include P53 pathway alterations like MDM2, MDM4 amplification, and epigenetic changes due to BCOR mutations and SYK upregulation [16, 17]. Rb1 gene mutations have been associated with >95% of RBs; however, there is a small subgroup of patients (2.7%) with RB with wild-type Rb1 and who were found to have MYCN amplification [18].

Retinoblastoma arises from the sensory retina and grows initially into the intraocular compartments like choroid, vitreous, and anterior chamber. There are two growth patterns of RB, exophytic (away from vitreous) and endophytic (towards vitreous). Exophytic RB arising from outer layers of retina results in subretinal seeds and retinal detachment. Endophytic RB arising from the inner retinal layers causes vitreous seeding. Other types of growth patterns include mixed (both endophytic and exophytic growth) and diffuse infiltrating orbital pattern. Patients with tumor extending into the anterior chamber can present with white fluffy exudates in the anterior chamber [19]. As there is a delay in diagnosis, it spreads to extraocular compartments involving the orbit, optic nerve, and distant metastatic sites.

4 Clinical Presentation

Two-thirds of the retinoblastoma cases are diagnosed before 2 years of age and 95% of cases diagnosed before 5 years of age [3]. There are two distinct patterns of clinical presentation. The majority of patients (60%) have sporadic, nonhereditary RB presenting with unilateral or unifocal disease and present at the median age of 30 months.The hereditary RB resulting in bilateral or multifocal disease occurs in 40% of patients [20] and presents earlier at a median age of 14–16 months.

Retinoblastoma patients with early intraocular disease present commonly with leucocoria (white eye reflex) in 70% followed by strabismus (15%) and nystagmus (10%). Leucocoria when clinically detectable without an ophthalmoscope indicates advanced intraocular disease occupying atleast 50% of retina (Fig. 1a). Strabismus occurs when RB involves macular region of the retina. Patients with advanced intraocular RB can present with rubeosis iridis, hyphema, hypopyon, and glaucoma. Retinoblastoma diagnosis should always be looked for in a child presenting with spontaneous hyphema in the absence of trauma or who presents with signs of endophthalmitis. Pain is uncommon in intraocular RB unless secondary glaucoma or inflammation is present. Extraocular RB presenting with proptosis (Fig. 1b), preauricular lymphadenopathy, bone pains, or central nervous system symptoms (headache, vomiting, seizures, etc.) is rare in developed countries [6]. However, one-third of RB in LMICs present with orbital disease or metastases and is the major cause of mortality, with the reported incidence ranging between 9% and 11% [21, 22].

Retinoma (or retinocytoma) is a spontaneously arrested/regressive form that resembles treated RB and on ophthalmoscopy appears as gray lesion with intense calcification and a zone of atrophy around the lesion. Retinocytoma can be detected in a parent of a child with RB. These lesions must be carefully monitored in young children, as they can occasionally progress to active RB [23, 24]. Differential diagnoses such as Coats disease, persistent hyperplastic primary vitreous, medulloepithelioma, uveal melanoma in children, retinal detachment due to other causes, *Toxocara canis* infection, etc. should be ruled out while evaluating a suspected RB [25].

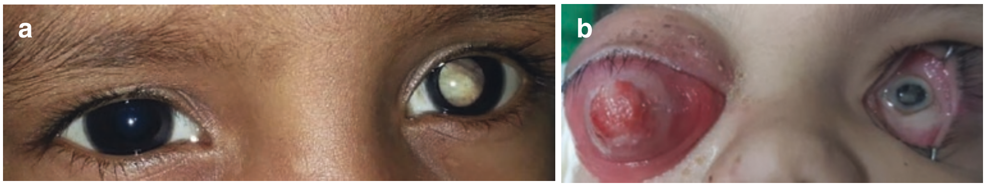

Fig. 1 Clinical manifestations of retinoblastoma (**a**) leucocoria in a case of left eye retinoblastoma (intraocular). (**b**) Advanced bilateral retinoblastoma; proptosis due to orbital (extraocular) retinoblastoma (right eye) and left eye pthisis bulbi

5 Evaluation and Workup

Retinoblastoma is a clinico-radiological diagnosis and biopsy is usually not required.

5.1 Examination Under Anesthesia (EUA)

Any child with suspected RB should undergo EUA for direct visualization of the tumor by the ophthalmologist who has the requisite experience in RB. Retinoblastoma appears as a mass projecting into the vitreous, but presence of retinal/vitreal hemorrhage or a corneal/lenticular opacity may make its visualization difficult. During EUA, the ophthalmologist should look for laterality (unilateral or bilateral), location of tumors (posterior/anterior), tumor size (diameter, thickness) and number, subretinal fluid and tumor seeds, vitreous seeds, iris neovascularisation, hyphema, hypopyon, and anatomic relationship of tumor to optic disc and macula. Additionally, evaluation of corneal diameters and intraocular pressure measurement should be done during the EUA session. A wide-angle retinal imaging systems such as RetCam provide a 130-degree field of view and digital recording and helps in diagnosis and monitoring (Fig. 2).

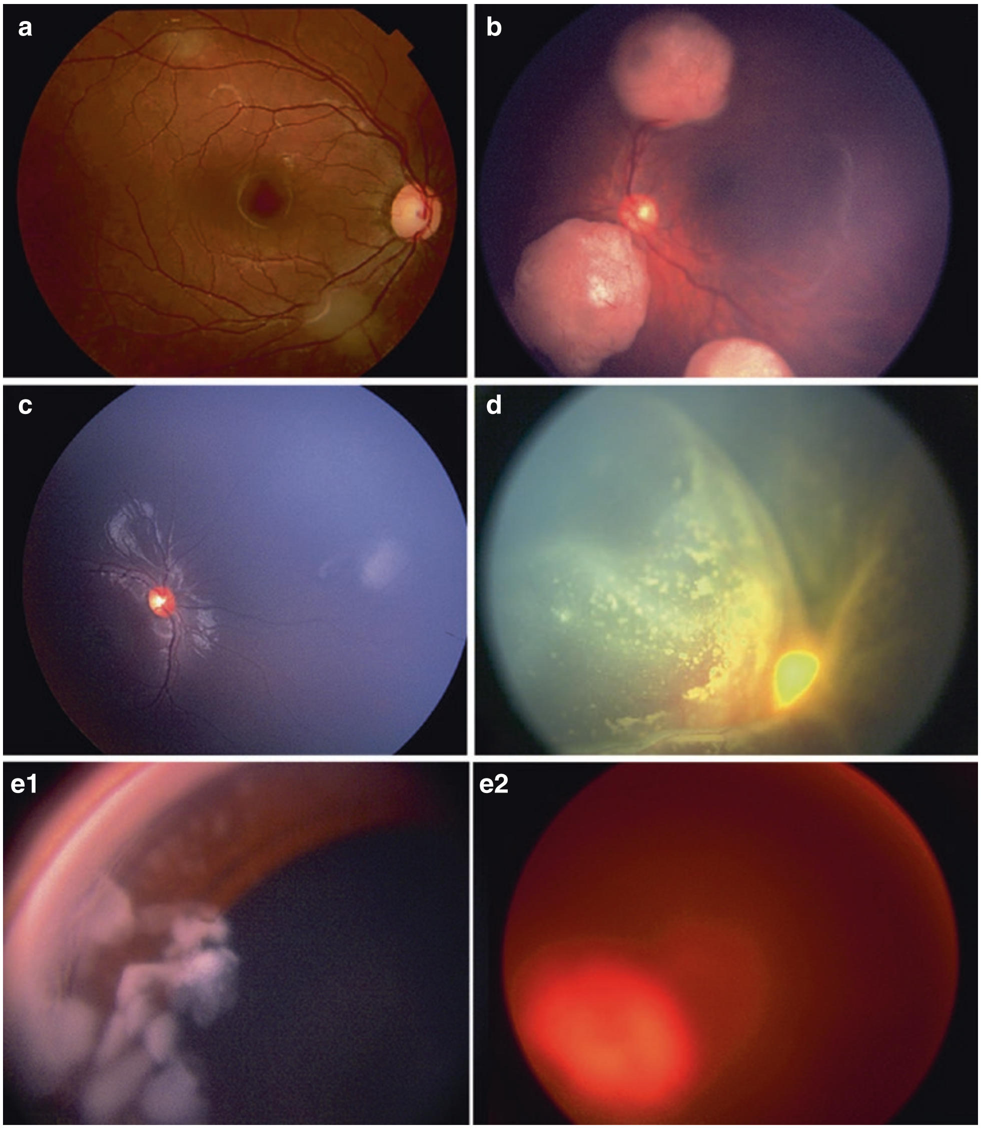

Fig. 2 RetCam imaging showing (**a**) intraocular ICRB Group A retinoblastoma, (**b**) Group B retinoblastoma—multiple endophytic tumors, (**c**) Group C retinoblastoma (**d**), Group D retinoblastoma with diffuse subretinal seeds, (**e1**) Group E retinoblastoma with anterior segment invasion, (**e2**) Group E retinoblastoma—large tumor with intraocular hemorrage

5.2 Ultrasonography (B-Scan)

Ultrasonography detects intra-tumoral calcification in 92%–95% of cases. The presence of calcification (Fig. 3) is key to diagnosis (present in 95% of RB) [26]. In case of RB, it can detect laterality, number, size and location of tumors, and RB-related complications like retinal detachment and vitreal hemorrhage. It also helps to rule out other causes of leucocoria like PHPV, Coats disease, retinopathy of prematurity, toxocariasis, and other infections.

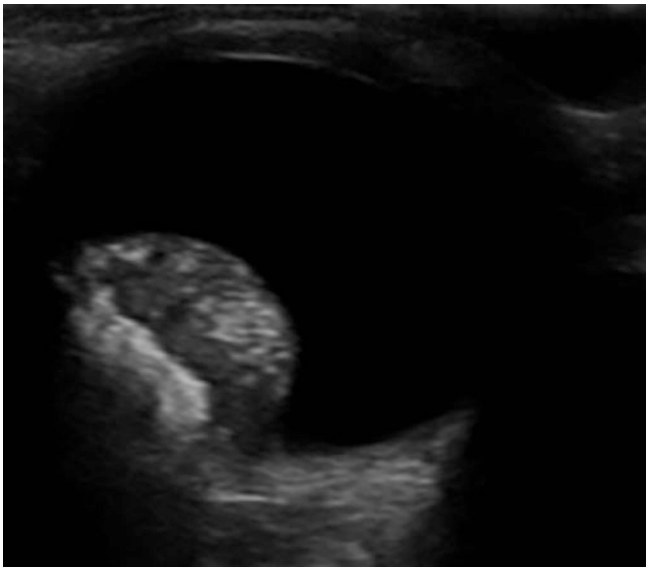

Fig. 3 Ultrasound showing intraocular mass with calcifications

5.3 MRI with Contrast

MRI of both orbits and brain with contrast is the imaging modality of choice for local staging. MRI gives an adequate resolution for the diagnosis of extraocular soft tissue disease (Fig. 4). Optic nerve involvement is indicated by abnormal contrast enhancement of the nerve, optic nerve thickening, and/or interruption of the normal linear enhancement at the optic nerve disc. Although MRI is an excellent modality for accurately assessing the extraocular extent of RB, EUA remains the optimal modality for assessing the intraocular component. However, MRI aids in detecting scleral and choroidal infiltration and pattern of tumor growth. Additionally, MRI brain is useful in detecting trilateral RB (pineoblastoma or suprasellar mass) and leptomeningeal disease. It is also a useful modality in differentiating RB from Coats disease and persistent hyperplastic primary vitreous [27].

CT scan is used occasionally in difficult cases to look for calcifications or else is only indicated if an MRI scan is not available.

5.4 Bone Marrow Studies and CSF Examination

Distant metastatic workup including bilateral bone marrow aspiration with biopsy and CSF studies should be considered in cases of advanced disease with evidence of extraocular RB at presentation or involvement of the optic nerve. Bone scan is rarely indicated in symptomatic patients only [28].

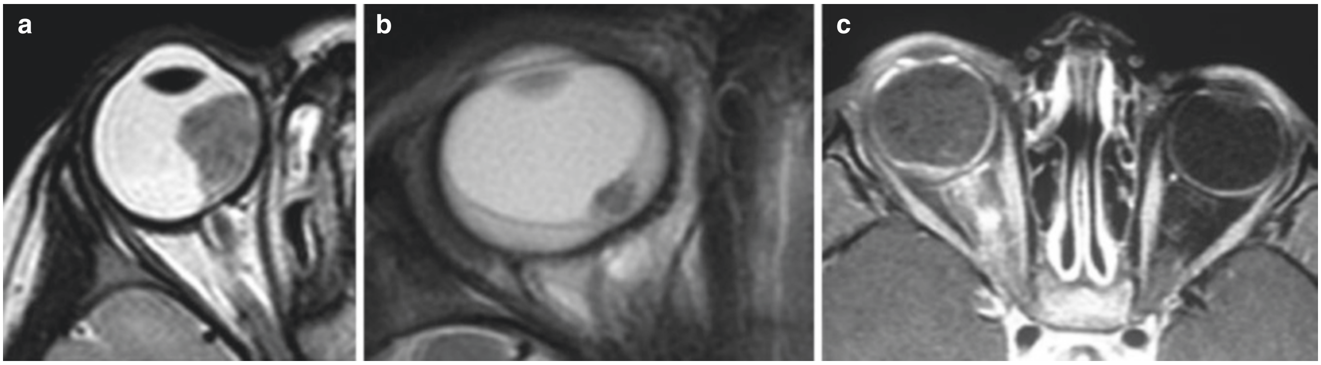

Fig. 4 MRI of orbit showing intraocular mass with endophytic (**a**), exophytic growth (**b**), and optic nerve (**c**) involvement

6 Grouping and Staging of Retinoblastoma

Risk stratification of RB includes two components: tumor grouping and staging.

Grouping System: For assessment of intraocular tumors and prognosticates globe and vision salvage

(a) Reese–Ellsworth Classification for Intraocular Tumors

This classification was introduced to prognosticate patients treated with methods other than enucleation. It predicts eye salvage with external beam irradiation [29]. The classification was devised before the widespread use of indirect ophthalmoscopy and evolution of focal treatments.

(b) International Classification of Retinoblastoma (ICRB, 2003) (Table 1)

This new classification is based on the extent of tumor seeding within the vitreous cavity and subretinal space, along with tumor size and location. This classification prognosticates vision. It also helps in predicting high-risk pathology [30].

Staging System: Prognosticates survival in RB.

(a) International Retinoblastoma Staging System (IRSS) (Table 2)

International Retinoblastoma Staging System (IRSS) has been proposed by an international consortium of ophthalmologists and pediatric oncologists (see Table 2). It is the more widely used RB staging system in the clinical setting [29, 31].

(b) American Joint Committee on Cancer (AJCC) staging system can be found in AJCC Cancer Staging Manual, Eighth Edition, Page no. 825–826, Chapter no. 68, Retinobhlastoma, Table: Definition of TNM which can be accessed at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5998398/The eighth edition of AJCC cancer staging system for Retinoblastoma includes a hereditary (H) component, making it the cTNMH scheme (c for clinical). The cTNMH categories are based on whether the retinoblastoma is determined to be intraretinal, intraocular, advanced intraocular or extraocular. The TNM scheme also has a pathological (pTNM) sub-classification that is widely used by ophthalmic pathologists [32]. AJCC RB classification is a comprehensive staging that incorporates intraocular and extraocular RB, with the power to predict both globe and life salvage especially in patients from developing countries where the majority present with advanced stage disease [33].

Table 1 International Classification of Retinoblastoma (ICRB)

Group	Definition
Group A	• Small intraretinal tumors away from foveola and disc All tumors that are 3 mm or smaller in greatest dimension, confined to the retina andall tumors are located further than 3 mm from the foveola and 1.5 mm from the optic disc
Group B	• All remaining discrete tumors confined to the retina All other tumors confined to the retina not in Group A Tumor-associated subretinal fluid less than 3 mm from the tumor with no subretinal seeding
Group C	• Discrete local disease with minimal subretinal or vitreous seeding Tumor(s) are discrete Subretinal fluid, present or past, without seeding involving up to one-fourth of the retina Local fine vitreous seeding may be present close to discrete tumor Local subretinal seeding less than 3 mm (2 DD) from the tumor
Group D	• Diffuse disease with significant vitreous or subretinal seeding Tumor(s) may be massive or diffuse Subretinal fluid present or past without seeding, involving up to total retinal detachment Diffuse or massive vitreous disease may include "greasy" seeds or avascular tumor masses Diffuse subretinal seeding may include subretinal plaques or tumor nodules
Group E	• Presence of any one or more of the following poor prognosis features: Tumor touching the lens Tumor anterior to anterior vitreous face involving ciliary body or anterior segment Diffuse infiltrating retinoblastoma Neovascular glaucoma Opaque media from hemorrhage Tumor necrosis with aseptic orbital cellulitis Phthisis bulbi

Table 2 International retinoblastoma staging system

IRSS Stage	Definition
0	Eye with no dissemination of disease and managed conservatively (refer to RB grouping)
I	Eye enucleated, completely resected histologically
II	Eye enucleated but with microscopic residual disease • Trans-scleral invasion • Positive cut end of optic nerve
III	Regional extension • Overt orbital disease • Pre-auricular or cervical nodal involvement
IV	Metastatic disease • Haematogenous metastasis • CNS extension – Pre-chiasmatic involvement – CNS mass – Leptomeningeal and CSF disease

7 Prognostic Factors

In unilateral RB, the prognosis for vision is very good for the unaffected eye, as the development of tumors in the unaffected eye is rare after 3 years of age. In bilateral RB, prognosis of vision depends on the extent of the tumor involvement and effectiveness of treatment modalities. The prognosis of vision in the involved eye is good if the tumors are small and away from the fovea. In cases of intraocular RB, the chances of ocular salvage decrease with more advanced disease, as in Groups D and E. In case of extraocular RB, survival is the goal of treatment and all patients will undergo enucleation of the involved eye with the addition of external beam RT and chemotherapy. The metastatic disease which occurs in~10% of RB patients from LMICs is associated with poor prognosis, especially CNS metastases [34].

7.1 Histopathologic Risk Factors

Histopathologic risk factors help in predicting the occurrence of metastasis in children with RB. Most important histopathologic prognostic indicators for development of metastasis include post-laminar optic nerve involvement at the site of surgical transection of the nerve and extrascleral extension of tumor into the orbit. As children in a developing country have delay in diagnosis, 54% of them present with such high-risk features compared to 20% of children in developed countries. Other high-risk histolo-pathologic features include massive choroidal invasion of ≥3 mm, post-laminar optic nerve involvement (PLONI) without cut end positivity [35, 36].

Escalation of treatment with adjuvant chemotherapy in the presence of these high-risk histopathologic features has shown to reduce the incidence of metastasis to 4%, compared to 24% who did not receive adjuvant therapy [37]. Also, a recent prospective study on high-risk histopathologic features in unilateral RB by COG found 3 mm or greater choroidal invasion in the peripapillary posterior choroid (around the head of the optic nerve) in combination with PLONI (≥1.5 mm) confer a poorer prognosis and lumbar puncture is recommended in such patients and if CSF negative for malignancy, orbital irradiation to be considered [38].

8 Genetic Testing and Genetic Counseling

Retinoblastoma is inherited in an autosomal dominant pattern with almost complete penetrance (85%–95%) [39]. Mutation in the Rb1 gene, located at 13q14.2, leads to loss of function that inactivates the Rb1 protein. In hereditary RB, germline mutation ("first hit") occurs mainly due to submicroscopic point mutations (75%–80% of cases) and large deletions involving the Rb1 gene, which can be detected by conventional cytogenetics is rare (3%–5%) [10]. Such large deletions involving 13q also lead to mental retardation, dysmorphism, and RB (13qdeletion syndrome) [40]. Somatic mutations (second hit) occur spontaneously at a rate of 1:1000. The majority of these mutations are chromosomal (50% mitotic recombination, 40% non-disjunction, and 10% deletions) [41]. These somatic mutations are more sensitive to radiation.

Genetic testing and counseling are indicated in all patients with RB and their families. Mutations are distributed throughout the 27 exons of the Rb1 gene. Suspected "hotspots" account for only 40% of these mutations. The rest of the mutations are scattered throughout the entire gene, most frequently in exons 9, 10, 14, 17, 18, 20, and 23 [42]. A single genetic test is unlikely to detect all germline RB gene mutation. Currently, it is necessary to combine various modalities such as DNA sequencing, FISH, MLPA, PCR, Methylation studies to increase the sensitivity of detection of Rb1 gene mutation to 90%–95%. Testing of the germline RB1 mutation is done on peripheral blood or saliva.

In patient with unilateral disease, tumor DNA can be used for detecting the two Rb1 gene mutations. The mutations identified in the tumor DNA can be sought in leucocyte DNA of peripheral blood or saliva of the patient. If one of the mutations is detected in the leucocyte DNA then it is a heritable form of RB. If neither of the mutation is identified in leucocyte DNA, then chances of it being heritable RB, cannot be conclusively ruled out due to the occurrence of low-level mosaicism. In such a scenario, proband's offsprings need to be tested for RB gene mutations detected in the tumor DNA, and genetic testing is not required in other family members. If tumor sample is unavailable and leukocyte DNA did not reveal a mutation, the chance for an undetected germline mutation is approximately 1% to 1.5%. In such a scenario, screening of the unaffected eye should occur until age 5. The offspring of such children should also undergo surveillance.

In bilateral disease, germline mutation can be identified in the leucocyte DNA in the peripheral blood/saliva in 95% of children. If the mutation cannot be identified in peripheral blood in a patient with bilateral disease and tumor DNA shows both mutations, low-level mosaicism is assumed and the proband's offspring is at risk of RB and needs surveillance [10]. If germline mutation is not identified by conventional methods and the patient has a positive family history, then linkage analysis can be used to clarify the mutation status of at-risk family members [43].

All future children of a proband with heritable RB have a 45% chance of developing RB (Table 3). Risks of RB for the siblings of the proband depend on parental status. If a parent has a history of RB, retinoma, or positive genetic testing

Table 3 Risk of developing retinoblastoma in siblings and offspring of patients

Subjects	Probability of disease (%)
Subjects with carriers of RB1 gene mutation	90
Offspring of patient with bilateral retinoblastoma	45
Sibling of patient (if either parent is affected)	45
Sibling of patient with bilateral disease (with parents unaffected)	2
Sibling of patient with unilateral disease (with parents unaffected)	1

results, future offsprings have a 45% risk of RB. If neither parent's testing reveals the familial RB1 mutation, subsequent children have a 2% to 3% chance of inheriting the mutation due to undetectable low-level mosaicism in one of the parents [39]. Any unaffected child with germline RB1 mutation should be examined every 3–4 weeks under anesthesia until the age of 1 and then every 3–4 months until the age of 5 years.

9 Principles of Management

Priorities in management of RB include cure, eye salvage, and vision preservation followed by prevention or early detection of second malignant neoplasms. Retinoblastoma management is a multidisciplinary approach including pediatric oncologist, ocular oncologist (ophthalmologist), radiation oncologist, genetic counselor, radiologist, pathologist, and other support staff. Retinoblastoma management must be individualized based on stage, group, and presence of bilateral disease. Major concepts in management include decisions regarding ocular preservation versus enucleation, avoiding or delaying radiation for ocular salvage, and risk-adapted therapies in extraocular versus intraocular RB.

9.1 Treatment Options

Treatment options include surgery (enucleation and orbital exenteration), focal therapies (laser photocoagulation, cryotherapy, thermotherapy, chemothermotherapy, and plaque radiotherapy), chemotherapy (intravenous, subconjunctival, intravitreal, and intra-arterial), and radiation (external beam irradiation and proton therapy).

9.1.1 Enucleation

Enucleation is the treatment of choice for advanced RB with tumor invading the optic nerve, orbit, and when there is no hope for salvage of useful vision in the affected eye. Enucleation involves gentle removal of the intact eye without seeding the malignancy into the orbit. Special care should be taken to perform all steps in a controlled fashion to avoid globe perforation or compression. For optimal staging, 10–15 mm long section of the optic nerve needs to be removed with the globe. During the same procedure an orbital implant is usually fitted, and the extraocular muscles are attached to it. Different orbital implants include polymethylmethacrylate, polyethylene, and coralline and bovine hydroxyapatite spheres. Implant motility with little resistance in the orbit is usually achieved by attaching the four rectus muscles anatomically to a tissue wrap placed around the implant. Judicious use of chemotherapy, surgery, and radiation therapy in patients with orbital disease usually results in effective tumor control, avoiding the need for orbital exenteration.

9.1.2 Focal Therapies

Laser Photocoagulation

Laser photocoagulation is used to treat small posterior RB of size ≤4.5 mm in diameter and ≤2.5 mm thickness with no evidence of vitreous seeds. Under indirect ophthalmoscopy, argon or diode laser is used to produce overlapping spots at the edge of the tumor in order to coagulate all the blood supply to the tumor [44]. Two to three sessions at 1-month interval are adequate to control 70% of properly selected tumors. Recurrences are treated with plaque radiotherapy [45]. Complications include serous retinal detachment, retinal vascular occlusion, retinal traction, retinal hole, and preretinal fibrosis.

Cryotherapy

Cryotherapy is used to treat peripheral small RB of size ≤3.5 mm in diameter and ≤2.5 mm thickness with or without overlying focal vitreal seeds. Cryotherapy causes cell lysis by disruption of the cell membrane that occurs after the formation of cytoplasmic ice crystals. Under direct visualization, nitrous oxide gas is used to deliver the trans-scleral freeze using a cryoprobe. One or two sessions of triple freeze–thaw cryotherapy at 1-month interval help in achieving tumor control [46]. Complications include serous retinal detachment, retinal tear, localized preretinal fibrosis, and rhegmatogenous retinal detachment.

Transpupillary Thermotherapy (TTT)

In transpupillary thermotherapy, ultrasound, microwaves, or infrared radiation delivers hyperthermia (45–65 °C) at subphotocoagulation temperatures, which results in tumor cytotoxicity. Under indirect ophthalmoscopy, semiconductor diode laser is used to deliver large spots (2–3 mm) with prolonged burn duration. The desired endpoint is a subtle whitening of the tumor free of hemorrhage. Complete tumor regression can be achieved in over 85% of tumors using three to four sessions of thermotherapy [45]. Thermochemotherapy is becoming a very important component in the treatment of intraocular RB where sequential administration of thermotherapy with carboplatin enhances the antitumor effect by increasing the platinum-DNA adducts [47]. Complications include focal iris atrophy, focal paraxial lens opacity, retinal scarring, retinal traction, and serous retinal detachment.

Plaque Radiotherapy

Plaque radiotherapy is a form of brachytherapy used to treat solitary RB with 6–15 mm diameter, ≤8 mm thickness, and lesion more than 3 mm away from the optic disc or fovea. The radioisotopes are loaded on an applicator (gold or silver) and the plaque sutured onto the episclera. The total dose of 40Gy is delivered over a period of 2–5 days. Commonly used radioisotopes include Iodine-125, Iridium-192 (emits gamma rays), and Ruthenium-106 (emits beta rays). In majority of cases (70%), it is used as secondary treatment after failure prior therapy [48]. Tumor control and globe salvage can be achieved in nearly 90% of cases. Positive visual outcomes have been reported in 62% of cases [49]. Plaque radiotherapy with focal, shielded radiation fields, has least chance of inducing second malignant neoplasm. Complications include radiation retinopathy and papillopathy especially in patients receiving systemic chemotherapy.

9.1.3 Systemic Chemotherapy

Successful management of RB using chemotherapy along with local surgical methods can reduce the need for external beam irradiation and therefore reduce the risk of second malignancies, orbital and facial growth abnormality due to radiation [50]. Systemic or intravenous chemotherapy can be administered in following three clinical settings.

Chemoreduction

The main objective of chemotherapy in localized intraocular RB has been to reduce the size of the tumors (chemoreduction) to an extent that would allow use of focal therapies and can eliminate the use of external beam irradiation and avoid enucleation. The commonly used chemotherapy regimen in intraocular RB contains vincristine, carboplatin, and etoposide (VEC regimen). Other chemotherapy agents which are active in RB include cyclophosphamide, doxorubicin, and cisplatin. Usually two to four chemotherapy cycles are used. Chemoreduction can be used in unilateral and bilateral RB and in all stages of disease, but advanced intraocular disease (GroupD/E) shows highest failure rate. Shields et.al showed chemoreduction success correlated with ICRB grouping with Groups A, B, and C attained over 90% control, whereas Group D showed only 47% control, and Group E was mostly enucleated [29]. There is increased risk of recurrence of retinal tumor and vitreal seeds in eyes with subretinal seeds at initial evaluation. These recurrences occur typically in the first 3 years [51]. In addition, at 5 years follow-up, 24% of patients develop new RB at a mean interval of 5 months, most commonly in patients with disease onset at infancy and family history of RB [52]. Careful follow-up of patients treated with chemoreduction is important.

Chemoprophylaxis

Chemoprophylaxis is given in patients with post enucleated specimens with high-risk histopathological features. The high-risk histopathological features may be associated with a higher risk of systemic metastasis and/or local recurrence and thus aim of chemotherapy is to reduce local/systemic relapse [37]. These high-risk histopathologic features include invasion of anterior chamber, iris invasion/ ciliary body invasion, transcleral invasion / extra scleral disease, and optic nerve resection margin positive [53]. However, observation for isolated massive choroidal invasion may be considered in centers where pathological expertise is available and the possible relapse could be salvaged. In centers where the facilities are not available, massive choroidal invasion must be considered as an indication for chemoprophylaxis. At least six cycles of chemotherapy is used in the presence of such high-risk pathologic features [54].

Chemoprevention

In patients in gross/microscopic residual extra-ocular disease, 6–12 cycles of chemotherapy is given along with external beam irradiation. Aim of chemoprevention is to rapidly reduce the tumor bulk and control the micrometastatic disease.

9.1.4 Local Delivery of Chemotherapy

Intra-arterial Chemotherapy (IAC)

IAC is a method of local delivery of chemotherapy for RB that results in high intraocular concentration of the drug without associated systemic adverse effects [55]. Through trans-femoral approach, the ostium of the ophthalmic artery is superselectively catheterized, and the bolus of chemotherapy is infused through the femoral catheter. Melphalan (3–7.5 mg), carboplatin (15–50 mg), and topotecan (1–2 mg) are the commonly used agents. IAC can be a one-, two-, or three-drug regimen based on the intraocular stage of the tumor. It is repeated every 4 weeks, and most of the patients require three sessions to achieve an adequate tumor response. The ocular salvage rate is around 90% for untreated eyes and around 60% for eyes that failed prior therapies [56]. Various studies comparing IAC with intravenous chemotherapy (IVC) suggest IAC leads to shorter time to success, lower number of relapses, improved ocular survival, and visual outcome [57]. However, the use of this technique requires unique resources including an interventional radiologist, pediatric anesthetic services, and an experienced ocular oncologist. Complications associated with IAC include vitreous hemorrhage, retinal artery obstruction, ophthalmic artery spasm with reperfusion, partial choroidal ischemia, optic neuropathy, etc.

Intravitreal Chemotherapy (IViC)

Vitreous seeds are aggregates of tumor cells found in the avascular vitreous. Vitreous seeds are relatively resistant to the effect of intravenous chemotherapy due to lack of blood supply. Refractory vitreous seeds are either persistent (does not disappear with chemoreduction) or recurrent (disappears during chemoreduction and recurs) [58]. Despite intra-arterial chemotherapy, vitreal seeds remain the main cause of secondary enucleation and indication for external beam irradiation. With intravitreal chemotherapy, higher drug concentration can be achieved within the vitreous, and it effectively causes regression of vitreous seeds, without associated systemic side effects. Melphalan (20–30 μg) and topotecan (20–30 μg) are the commonly used agents in IViC. After injecting the drug, the application of triple freeze–thaw cryotherapy at the injection site prevents the egress of the tumor cells in the needle track [59]. With melphalan, vitreous seed regression ranging from 85% to 100% of eyes and globe salvage in 80%–100% of eyes have been reported. By combining intra-arterial and intra-vitreal chemotherapy in advanced intraocular disease, it is possible to reduce the treatment duration, cost, and reduce the need for enucleation and external beam irradiation.

Intracameral Chemotherapy (ICC)

ICC is a novel conservative method of delivering chemotherapy directly into the anterior chamber in selected cases of eyes with secondary anterior chamber seeding, with encouraging results. However, longer follow-up is needed to assess safety and efficacy [60].

9.1.5 External Beam Irradiation (EBRT)

Retinoblastoma is a highly radiosensitive tumor. With the advent of chemotherapy, the role of radiotherapy is very limited in the primary management of RB. External beam irradiation induces second cancers in the field of irradiation. In cases of bilateral RB, the cumulative incidence of second cancers at 50 years is reported to be 51% based on a very large series from New York [61]. It can also lead onto orbital hypoplasia, cataract, and dry eye syndrome.

Currently, EBRT is used in patients presenting with advanced RB such as overt orbital disease and intraocular RB not responding well to conservative management, especially with diffuse vitreal and/or subretinal seeds, when globe salvage is the priority and after enucleation with high-risk features (transscleral involvement and an optic nerve cut end involvement). The ideal dose is 40–45 Gy given in fractionated doses of 180–200 cGy over 3–4 weeks with lens-sparing technique with photon beam delivered using linear accelerator [62]. Proton therapy is a recent modality of EBRT with early reports showing encouraging results [63]. Sethi et al. in their retrospective series showed, in patients who received proton therapy there was 0% 10-year cumulative incidence of second malignant neoplasm in the RT field compared to 14% in photon therapy. Overall second malignant cancers were 5% in proton therapy arm compared to 14% in photon therapy [64].

10 Tata Memorial Hospital Management Algorithms for Retinoblastoma (Figs. 5 and 6)

10.1 Treatment of Extraocular Retinoblastoma

10.1.1 Orbital Retinoblastoma

For patients with macroscopic orbital disease, two to four cycles of chemotherapy are administered upfront followed by enucleation. Additional cycles of adjuvant chemotherapy (total of 12 cycles) are administered [65]. Adjuvant orbital irradiation (40–45 Gy) is required to consolidate local control. If there is a recurrence after the above treatment, orbital exenteration should be considered. Patients with isolated involvement of optic nerve at the transection level require a similar treatment approach and irradiation should include entire orbit (36 Gy) with 10 Gy boost to the optic chiasm. In cases of pre-auricular and/or cervical nodal involvement irradiation to the involved nodes should be carried out. Patients with accidental ocular perforation or intraocular surgery for unsuspected RB should be managed in line with orbital RB.

10.1.2 Retinoblastoma with Systemic Metastasis

Patients with involvement of central nervous system (including trilateral RB) have a very poor outcome and most succumb to their disease despite intensive systemic chemotherapy and intrathecal chemotherapy. Therapy intensification with high-dose chemotherapy with autologous stem cell rescue also has not shown to improve outcomes. However, in metastatic RB not involving CNS (isolated hematogenous metastasis), high-dose chemotherapy with carboplatin, etoposide, and thiotepa followed by autologous SCT has shown to improve outcome in a recent Children Oncology Group (COG) prospective study with 3-year EFS of 79% [66].

11 Long-Term Effects of Retinoblastoma Therapy

11.1 Second Malignant Neoplasms (SMN)

Cumulative incidence of SMN in patients with germline mutations of the Rb1 gene increases with age. SMNs are the most common cause of mortality in survivors of bilateral disease. Patients with family history of RB have a higher cumulative incidence of second neoplasms compared with bilateral RB children without a family history. Patients with sporadic RB are not at increased risk. For hereditary retinoblastoma, the greatest risk is neoplasms of bone (osteosarcoma), connective and soft tissue (leiomyosarcomas), eye, orbit, and nasal cavities. Patients also have increased risk of developing pineoblastoma, melanoma, CNS malignancies, and neoplasms of buccal cavity and uterus. The lowest risk is for neoplasms of lung, breast, and colon [67]. The median age at diagnosis of second neoplasm is 15–17 years. Survivors of a second neoplasm appear to have an increased risk of third and fourth malignancy that occurs at shorter intervals. Cumulative incidence of the third neoplasm is 22% at 10 years from the diagnosis of second cancer and it occurs at a median of 5.8 years [68].

Radiation results in an increased incidence of second cancers especially in patients with hereditary RB. The cumulative probability of developing SMN in patients with germline RB1 gene mutation is 38% when treated with radiation versus 21% without radiation. Children receiving radiation during their first year of life have a higher risk of developing SMN. The risk of therapy-related leukemia is minimal as the cumulative doses of etoposide and other topoisomerase inhibitors used in the treatment of RB are relatively low.

11.2 Impaired Orbital Growth

As children develop RB at a young age and orbital growth is still in progress, enucleation and/or orbital irradiation results in orbital growth impairment as the child reaches adolescence ('hourglass' facial deformity). Final orbital volumes after enucleation depend on the size of the orbital implant. In bilateral RB, the goal of therapy is to delay radiation that may allow more complete orbital and facial growth [69].

11.3 Visual Outcome

Visual outcome correlates with the intraocular stage and tumor location. Visual acuity of 20/40 or better can be achieved in 90% of eyes with tumors away from the macula and in 24% of eyes with macular tumors [70, 71]. Since RB affects the visual system at an early age when CNS is still developing, the final visual outcome is determined by the extent of the disease itself and/or treatment-induced damage in the visual pathways.

Rare Pediatric Tumors

Subramaniam Ramanathan, Nirmalya Deo Pradhan,
and Girish Chinnaswamy

Abbreviations

ACC	Adrenocortical carcinoma
DHEA-S	Dehydroepiandrosterone sulfate
DSRCT	Desmoplastic small round cell tumor
HiPEC	Hyperthermic peritoneal perfusion
LFS	Li–Fraumeni syndrome
NPC	Nasopharyngeal carcinoma
PPB	Pleuropulmonary blastoma
TNM	Tumor–node–metastasis
UESL	Undifferentiated embryonal sarcoma of liver

1 Definition, Incidence and Caveats

Current data puts the global incidence of childhood cancer in children aged 0–14 years to be 140.6 per million years [1]. Pediatric cancer in itself is thus a rare disease. Several pediatric oncology investigative groups across the globe have defined which tumor qualifies to be under the rubric of "rare pediatric tumor."

1. TREP (Tumori Rari in Eta Pediatrica) [2]: Italian collaborative group formed in 2000, defined pediatric very rare tumors (VRTs) as "any malignancy characterized by an annual incidence of <2/million in population up to 18 years." Based on this, they identified 297 patients over a 5-year period across 45 centers in Italy. Liver tumors weren't included in this group as they were being studied by the SIOPEL group. Also, germ cell tumors (GCTs), retinoblastomas, rare nonrhabdomyosarcoma (RMS) soft tissue sarcomas also were excluded as they had their own therapy protocols.
2. Rare Tumor Working Group (UK Children's Cancer & Leukemia Group) [3]: Rare tumor was defined as age-standardized annual incidence of less than 1/million children in the UK. Melanomas and GCTs were excluded. Between 1991 and 2000, 766 cases were recorded, which comprised of 5% of all childhood cancers.
3. German Childhood Cancer Registry (GCCR) [4]: Retrospective audit conducted between 2001 and 2010; any tumor having an incidence of <0.3% of all malignancies were defined as rare. Overall, 232 patients were identified in children less than 15 years.
4. European Cooperative Study Group for Pediatric Rare Tumors (ExPERT) [5]: Formed in 2008, by collaboration of groups from Italy (TREP), UK, Germany (GCCR), France (FRACTURE) and Poland. Defines rare tumor as "any solid malignancy or borderline tumor characterized by an annual incidence of <2/million and/or not already considered in clinical trials." This definition encompasses both the epidemiological (defined by incidence) and clinical (rare adult cancers that may arise in childhood) aspects of rare cancers. Since then, the ExPERT group has published incidence rates and treatment outcomes on selected tumor groups [6–10].
5. Infrequent Tumor Working Group–Children's Oncology Group (COG) [11]: In order to streamline the enrollment of rare tumors and make the group more qualitative, numerical cut-off was dropped from the criteria and instead defined rare tumor as "other malignant epithelial neoplasms and melanomas" in the International Classification of Childhood Cancer subgroup 11 of the SEER Database. While including thyroid cancers and melanomas (excluded by previous groups), this definition excluded pancreatoblastoma (PB) and pleuropulmonary blastoma (PPB).

Despite the efforts to classify rare tumors under a single umbrella, several hurdles exist in extracting prognostic and therapeutic data on these tumors. These “orphan diseases” may be inappropriately classified, diagnosed and treated. Coding errors may inadvertently misclassify these diseases under adult oncology registries because of their higher prevalence in the adult age group [12].

The COG Every Child Project represents a new approach to support clinical and biologic research for rare tumors and will allow identification of patients, submission of biologic specimens, and provide status updates for children seen at a COG institution [13].

2 Profiles of Rare Tumors

Covering the entire gamut of pediatric rare tumors is beyond the scope of this chapter. While the entire list is outlined in Table 1 [14, 15], important tumors among these are described below.

Table 1 List of rare tumors in children

System involved	Type of cancer
Head and neck region	*Nasopharyngeal cancer*
	Esthesioneuroblastoma (olfactory PNET)
	Thyroid tumors
	Oral cavity cancer
	Salivary gland tumors
	NUT midline carcinoma
Thoracic cancers	Breast cancer
	Tracheobronchial tumors
	Pleuropulmonary blastoma
	Esophageal cancer
	Thymoma and thymic carcinoma
	Cardiac tumors
	Mesothelioma
Abdominal cancers	*Adrenocortical carcinoma*
	Gastric cancer
	Pancreatoblastoma
	Desmoplastic small round cell tumor (DSRCT)
	Colorectal cancer
	Gastrointestinal carcinoid
	Gastrointestinal stromal tumor (GIST)
Genital/urinary cancers	Bladder cancer
	Nongerm cell gonadal tumors
	Cervical and vaginal cancer
Other rare tumors	Multiple endocrine neoplasia (MEN) and carney complex
	Pheochromocytoma and paraganglioma
	Melanoma
	Nonmelanomatous skin cancer
	Chordoma

2.1 Nasopharyngeal Carcinoma

2.1.1 Epidemiology

Accounting for 35–50% of all nasopharyngeal cancers, nasopharyngeal carcinoma (NPC) is relatively rare in children, with only 1% of all cases occurring in less than 19 years. It is an endemic cancer with a higher prevalence in well-defined ethnic groups in Hong Kong, China and Alaskan Eskimos [14]. It shows bimodal age distribution with an early peak at 10–20 years and a late peak at 40–60 years.

2.1.2 Risk Factors

1. Epstein–Barr virus infection: EBV is strongly associated with NPC. Apart from its oncogenic potential (described below in pathogenesis; Fig. 1), circulating levels of EBV-DNA and serological documentation of EBV-DNA infection may aid in the diagnosis [16].
2. HLA subtype: HLA A2Bsin2 haplotype is associated with a higher risk of NPC [17].

2.1.3 Histology and Pathogenesis

NPC originates from the surface epithelium of the fossa of Rosenmüller and can be categorized into three distinct histological subtypes.

- Type I (sporadic): Keratinizing squamous cell carcinoma similar to other cancers of the head and neck region. Etiologically, this is related to alcohol and tobacco exposure and is more common in adults.
- Type II: Nonkeratinizing variety of SCC. It is further subclassified into IIa and IIB on the basis of lymphoid infiltration.
- Type III (endemic): Undifferentiated variety. It is the most common subtype seen in childhood NPC. It is secondary to virological/environmental risk factors and genetic susceptibility. It is more common in children and almost universally associated with EBV infection.

2.1.4 Clinical Presentation

- Usually presents in the second decade of life (13–15 years) with a male preponderance.
- In comparison to adults, children have larger primaries, present with a more advanced disease and higher nodal stage. Despite this, children overall have a better prognosis.
- Symptoms are related to local spread and distant metastases.
- Local spread: epistaxis (unilateral > bilateral), congestion, otitis media, trismus
- trotter’s triad: triad of conductive deafness (due to Eustachian tube block), ipsilateral temporoparietal neu-

Fig. 1 Step-wise oncogenesis secondary to EBV infection in the nasopharyngeal mucosa

Overexpression of LMP-1
Activation of NF-K-B pathway
NF-K-B upregulates the expression of factors like VEGF/FGF-2/MMP-9/COX2
ONCOGENESIS

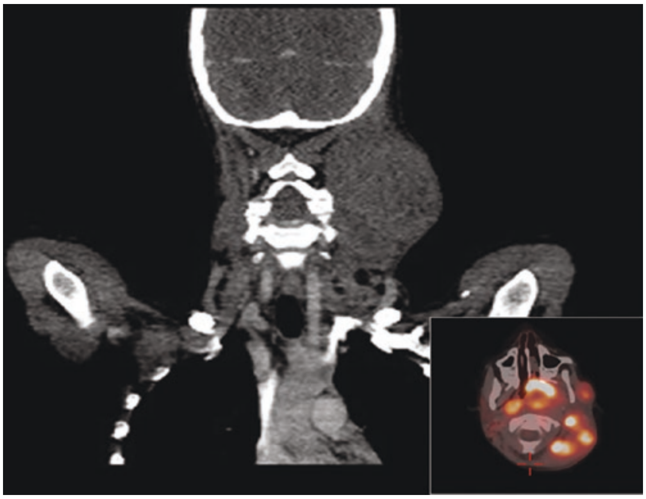

Fig. 2 Coronal view showing a large cervical nodal mass with inset showing PET avidity in both the nasopharyngeal and neck regions

ralgia (due to trigeminal nerve involvement) and ipsilateral palatal paralysis (due to vagus nerve damage).

- Skull-base erosion causes severe headache.
- Bilateral bulky nodes can occur in 80% patients and may be the only presenting feature.
- Distant spread to bones, lungs and liver is not uncommon with up to 90% patients in endemic regions presenting with Stage III/Stage IV disease vis-à-vis in nonendemic regions where the incidence is 77% [18].

2.1.5 Diagnostic Work-Up

- Diagnostic nasal endoscopy + biopsy of the primary mass OR biopsy of the cervical lymph node
- MRI of the head and neck region extending to the supraclavicular region
- CT scan to define skull base erosion
- CT Chest to evaluate parenchymal metastases and mediastinal nodal disease
- If available, FDG-PET CT can be a single diagnostic modality for staging of disease (Fig. 2).
- Audiogram at baseline to document deficits and also on follow-up
- Thyroid function tests at baseline and at follow-up

2.1.6 Staging and Therapy

The tumor–node–metastasis (TNM) classification of the American Joint Committee on Cancer is used to determine the tumor stage.

In view of its inaccessible location and anatomical site, surgery has a limited role. Therapy of childhood NPC is with an "intent to cure." Treatment options are as follows:

1. **Radiotherapy** alone in early stage disease: In Stage I disease, radiotherapy alone is adequate treatment. Majority of children do not come under this category, and hence, concurrent chemoradiation or induction chemotherapy followed by definitive radiation is the treatment of choice [19].
2. **Combination Chemotherapy and Radiation**: Chemotherapy agents with best single-agent activity include methotrexate, cisplatin, bleomycin, 5-fluorouracil and carboplatin [14]. Some of the chemotherapy regimens that have been employed are:
    (a) **BEP:** Bleomycin 15 mg/m^2 IV bolus on Day 1 and 12 mg/m^2 as a 24-h infusion on Days 1–5; Epirubicin 70 mg/m^2 in a 1-h infusion on Day 1; Cisplatin 100 mg/m^2 in a 4-h infusion on Day 5.
    (b) **PF:** Cisplatin 100 mg/m^2 as a 4-h intravenous infusion on Day 1 OR 20 mg/m^2/day on Days 1–5; Fluorouracil 1 g/m^2 as a 24-h infusion on Days 1–5 (Leucovorin 25 mg/m^2 given for 6 days to potentiate 5-FU action).
    (c) **MPF:** Methotrexate 120 mg/m^2 as intravenous infusion on Day 1; Cisplatin 100 mg/m^2 in a 4-h intravenous infusion on Day 2; Fluorouracil 1 g/m^2 in a 24-h infusion on Days 1–5 (Leucovorin 25 mg/m^2 given for 6 days to potentiate 5-FU action).
    (d) **BMP:** Cisplatin 100 mg/m^2 as a 4-h intravenous infusion on Day 1 OR 20 mg/m^2/day on Days 1–5; Methotrexate 50 mg/m^2 as intravenous infusion on Days 1, 8, 15. Bleomycin 20 IU/m^2 IV bolus on Days 1, 8 and 15.

While the majority of American and European protocols use a combination of 5-FU and Cisplatin as chemotherapy, the authors' center uses a modified BMP regimen [20]. The survival outcomes of various groups in NPC are tabulated below in Table 2. Survival outcomes were comparable with European

Table 2 Survival outcomes of nasopharyngeal carcinoma treated by various cooperative groups

Group/Protocol	Chemotherapy regimen	Number of patients	Concurrent chemoradiation	EFS/OS
TREP project, Italy [21]	PF	46 children	Yes (cisplatin)	79.3%/80.9%
Rare Cancer Network (RCN) [22]	Multicenter study (70% protocols were CDDP-based)	165 (nonmetastatic)	Yes	68.8%/77.4%
Tata Memorial Hospital [20]	BMP	81 children	No	68%/73%
ARAR0331, Children's Oncology Group [23]	PF	111	Yes (cisplatin)	84.3%/89.2%
NPC-2003, German POH [24]	PF + interferon 1β	45	Yes (cisplatin)	92.4%/97.1%

Abbreviations: *PF* Cisplatin + 5-fluorouracil, *BMP* Bleomycin, methotrexate and cisplatin

data demonstrating a 5-year PFS/OS of 79.3%/80.9% [21] and the COG data showing 5-year EFS/OS of 84.3%/89.2% [23]. German investigators have used interferon 1β (100,000 IU/kg as iv infusion thrice a week for 6 months) after a Cisplatin–5FU backbone and have noted a EFS/OS of 92.4%/97.1% at a follow-up of 30 months [24]. The rationale for employing IF-1β is because of its putative antiviral activity against EBV. All these regimens used concurrent chemoradiation with Cisplatin during weeks 1 and 3 of RT.

2.1.7 Doses of Radiation

Nasopharyngeal carcinoma is a radiosensitive disease and RT is the primary modality of therapy. The regional nodes in the entire head and neck area are also irradiated and structures surrounding the nasopharynx and entire neck should also be irradiated [14]. Type III nasopharyngeal cancers are most radiosensitive.

Recommended doses for the primary site and other involved nodal sites range from 59.4 to 70 Gy (1.8–2 Gy per fraction) and some studies have shown improved local control when doses >66 Gy are used [22].

2.1.8 Late Effects

Common long-term morbidities seen in survivors of childhood NPC are neuroendocrine sequelae (encephalopathy, thyroid dysfunction and pituitary dysfunction), hearing deficits, oral and dental effects (xerostomia, dental malocclusion, glossolalia, trismus) and neck fibrosis.

All of these are RT dose related, and hearing deficits can be compounded due to the use of Cisplatin.

Cochlear sparing RT (limiting the dose to cochlea to 45 Gy), Parotid sparing RT, use of amifostine (to reduce xerostomia) are some of the approaches to reduce these late effects.

2.2 Pleuropulmonary Blastoma

2.2.1 Epidemiology

Pleuropulmonary blastoma (PPB) is an embryonal tumor arising from the thoracopulmonary mesenchyme, which occurs exclusively in toddlers and young children, presenting either as a parenchymal or pleural mass.

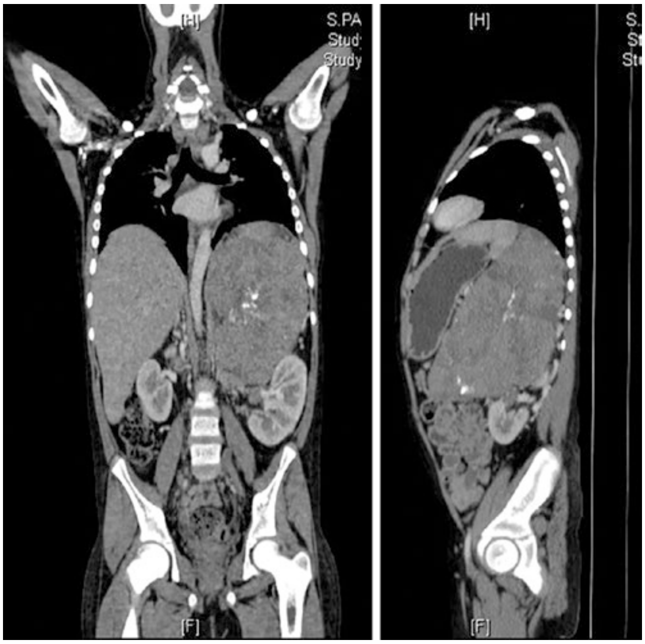

Fig. 3 Coronal and sagittal views of an adrenocortical carcinoma (well-demarcated lesion with stippled calcification)

PPB is strongly associated with germline mutations of DICER-1.

PPB is a rare tumor and the PPB registry forms an important source of information on the types and outcomes of this tumor [25].

2.2.2 Classification

PPBs are classified histologically as Type I, II and III as per Dehner's classification [26] with Type I being completely cystic, Type III being entirely solid (Fig. 3) and Type II representing a transition between the two. The clinical demographic and survival characteristics are outlined below (Table 3) [25]:

2.2.3 Prognostic Factors

- Complete resection at diagnosis is a favorable prognostic factor
- Doxorubicin containing regimens produced a better outcome in Type II/III PPBs.

Table 3 Clinical features of pleuropulmonary blastoma

	Type I	Type II	Type III
Histology	Purely cystic neoplasm with subtle malignant changes	Cystic and solid components	Purely solid with blastemal and sarcomatous components
Median age	8 months	35 months	40 months
Relative proportion	33%	35%	27%
Anaplasia	<10%	60%	70%
Distant metastases	<5%	7%	10%
DICER1 mutation	62%	63%	75%
5-year survival	89%–100%	71%	53%
Role of chemotherapy	Questionable if completely resected	Needs anthracycline-based chemotherapy	

- Type I fared better compared to Type II/III [7].

Across all the types of PPB, DICER1 mutation was noted in two-thirds of patients. Apart from PPB, DICER1 mutation is associated with a varied spectrum of solid tumors viz. cystic nephroma/Wilms tumor, sex cord stromal tumors, multinodular goiter, pinealoblastoma, medulloepithelioma, juvenile intestinal polyps and seminoma [27].

Role of DICER1: DICER1 encodes a 218 kD ribonuclease III endonuclease that participates in generation of mi-RNA. Mutated DICER1 or loss of DICER1 causes retention of abnormal mi-RNA sequences leading to disruption in branching morphogenesis and mesenchymal expansion [27]. Presence of germline DICER1 mutation has no prognostic impact on PPB.

In children with a known DICER1 pathogenic variant, clinical and radiographic screening guidelines for PPB (and other tumors) have been recommended [27]: Chest radiograph at birth and every 4–6 months until 8 years of age, yearly from 8 to 12 years of age. CT scan to be considered (with dose optimization) at 3–6 months of age. If mutation is detected after 12 years, a baseline chest radiograph or CT scan is recommended.

2.2.4 Clinical Features

Children present with nonspecific symptoms of fever, malaise and abdominal pain. Chest symptoms include respiratory distress, cough and pneumothorax.

The majority of lesions are right-sided (60%); one-third have bilateral disease.

Symptoms of distant spread include headache, irritability and vomiting. Cerebral metastases are frequent both at diagnosis and relapse, with a cumulative probability of 11% and 54% at 5 years for Type II and III PPB, respectively [28].

2.2.5 Diagnostic Work-Up

1. CT/MRI of the primary chest mass (see Fig. 3)
2. Bone scintigraphy by Tc99-diphosphonate
3. FDG-PET/CT scan (if available)—single diagnostic and staging modality
4. CT scan of head

2.2.6 Therapy

Complete surgical clearance (wedge excision, lobectomy or pneumonectomy) forms the cornerstone of cure. As per the histologic type, the PPB registry and ExPERT committee has demonstrated the following outcomes [7, 25]:

- Type I: Surgery is the treatment of choice with a 5-year DFS/OS of 82%/91%.
  - 10% may progress to Type II/Type III.
  - Adjuvant chemotherapy does not appear to have any impact on rate of progression.
- Type II/III: Sarcoma-like therapy with doxorubicin-based regimens
  - 5-year DFS/OS: Type II: 59%/71%; Type III: 37%/53%.
  - Approximately, half of these tumors relapsed in the CNS.

2.3 Adrenocortical Carcinoma

2.3.1 Epidemiology

Adrenocortical carcinoma (ACC) is a rare but aggressive endocrine neoplasm arising from the fetal zone of the fetal adrenal cortex. It has a bimodal age of distribution with peaks in the first and fourth decades with a female predilection [29]. A number of tumor syndromes are closely associated with ACC; notable among these are Li–Fraumeni syndrome (LFS), Beckwith–Weidemann syndrome, Carney complex, Lynch syndrome and MEN-1 [14].

Annual incidence in US is 0.2–0.3 cases/million. It is most prevalent in Southern Brazil. The reason for this clustering is a high prevalence of R337H germline mutation in the TP53 tumor suppressor gene [14]. Genomic landscape of ACC shows presence of IGF2 overexpression (most common genomic alteration), presence of TP53 mutations, ATRX mutations and beta-catenin mutations.

2.3.2 Clinical Features

The IPACRT registry and a single center study in southern Brazil provide valuable information on the clinical profile of ACC [30, 31].

Median age at diagnosis was 3.2 years with a female predilection. As it is a hormone secreting tumor, the clinical manifestations follow the nature of hormone secreted. The most common pattern is virilization (either isolated or in combination). Table 4 shows the clinical features, hormonal profile and the relative incidence of each [32]. Small secretory ACCs can potentially lead to endocrine manifestations and precede the onset of an abdominal lump. Certain scenarios must alert the clinician to the possibility of ACC in a child [32].

- To avoid delaying the diagnosis of ACC, the clinician should consider any child younger than 4 years with pubarche (pubic hair) to have ACC and refer early.
- Unexpected somatic growth in the context of an abdominal lump must point toward possibility of ACC.
- Presence of acne on an infant can be considered pathognomonic of an adrenocortical lesion.
- Cushing syndrome is very rare in children, it should be considered highly indicative of ACC in children younger than 10 years.

2.3.3 Diagnostic Work-up

- Elevated levels of urinary keto-steroids and plasma dehydroepiandrosterone sulfate (DHEA-S).
- Urinary DHEA concentration and 17-hydroxycorticoid levels are less sensitive.

These hormonal assays provide a clue to the diagnosis and also aid in monitoring after completion of therapy.

- MRI of the abdomen/CT abdomen can delineate the regional extent of the tumor (Fig. 4)
- CT Chest + bone scintigraphy for staging.
- FDG-PET/CT (not validated, but act as a single investigation to assess locoregional and distant spread).
- Staging of ACC is largely surgical, based on COG and takes into account tumor volume and resectability [32].
  - *Stage I:* Tumor totally excised, tumor size <100 g or 200 mL, absence of metastasis and normal hormone levels after surgery
  - *Stage II:* Tumor totally excised, tumor side >100 g or >200 mL, absence of metastasis and normal hormone levels after surgery
  - *Stage III:* Unresectable tumor, gross or microscopic residual tumor, tumor spillage during surgery, persistence of abnormal hormone levels after surgery, or retroperitoneal lymph node involvement
  - *Stage IV:* Metastatic disease

Table 4 Clinical spectrum of adrenocortical carcinoma

Clinical feature	Hormone	Frequency
Virilization Pubic and facial hair Clitoral hypertrophy Hoarseness of voice Accelerated growth	Dehydroepiandrosterone Androstenedione Dehydroepiandrosterone sulfate Testosterone	45%–50%
Mixed Symptoms of virilization and Cushing syndrome	2 or more hormones (increased cortisol and androgens)	45%–50%
Cushing syndrome Moon face, buffalo hump, hypertension	Cortisol Deoxycortisol	5%–8%
Nonfunctional Abdominal mass	Elevated adrenocortical hormones	5%–8%
Feminization (gynecomastia in males and pseudopuberty in females)	Estradiol, Estrone, Estriol	<1%
Conn syndrome	Aldosterone	<1%

2.3.4 Treatment

Treatment of ACC is surgery with the extent of surgical resection having a prognostic impact on the outcome. Chemotherapy is used in locally advanced and metastatic disease. Chemotherapy regimens consist of Cisplatin, Etoposide, Doxorubicin and Mitotane [33].

Mitotane (an insecticide derivative) a nonclassical antineoplastic agent, noted to cause adrenal necrosis in animals [3], has been used in combination with chemotherapy. But a narrow therapeutic window (requires drug monitoring with levels between 14 and 20 mg/L) and consequent serious side effects are issues that limit its efficacy [34].

The 5-year survival ranges from 70% to 80% in localized disease to 43%–65% in locally advanced disease and 10%–20% in metastatic disease [35]. Apart from conventional prognostic factors like tumor volume, extent of resection, presence of metastatic disease, overexpression of Ki-67 ligand (≥15%) is a strong prognostic indicator linked to adverse outcome [35]. A recent landmark phase II study in 39 patients with unresectable or metastatic ACC, explored the role of Pembrolizumab (anti-PD1 monoclonal antibody) at a dose of 200mg every 3 weeks, to assess objective remission rate. The disease control rate (percentage of patients who demonstrated objective response or stable disease) was 52% (95% CI, 33% to 69%). While most patients with objective responses in this study (78%) did not have Lynch syndrome and had microsatellite-stable (MSS) tumors, 2/6 (33%) of the MSI-high (MSI-H) or MMR-deficiency (MMR-D) tumors did demonstrate partial response [36]. Despite the study including mostly adults (median age: 19–87), it provides encouraging proof of role of targetted therapies in a group of tumors with otherwise poor survival rates. It also highlights the importance of testing patients of microsatellite instability and mismtach repair deficiency.

2.3.5 Follow-up

As nearly two-thirds of patients with ACTs are linked to genetic predisposition, referral to a cancer genetics department is mandatory for genetic counseling, screening for second neoplasms and family follow-up.

Regular surveillance with clinical examination, ultrasound abdomen, estimation of urinary/plasma hormone profiles are necessary to identify recurrence.

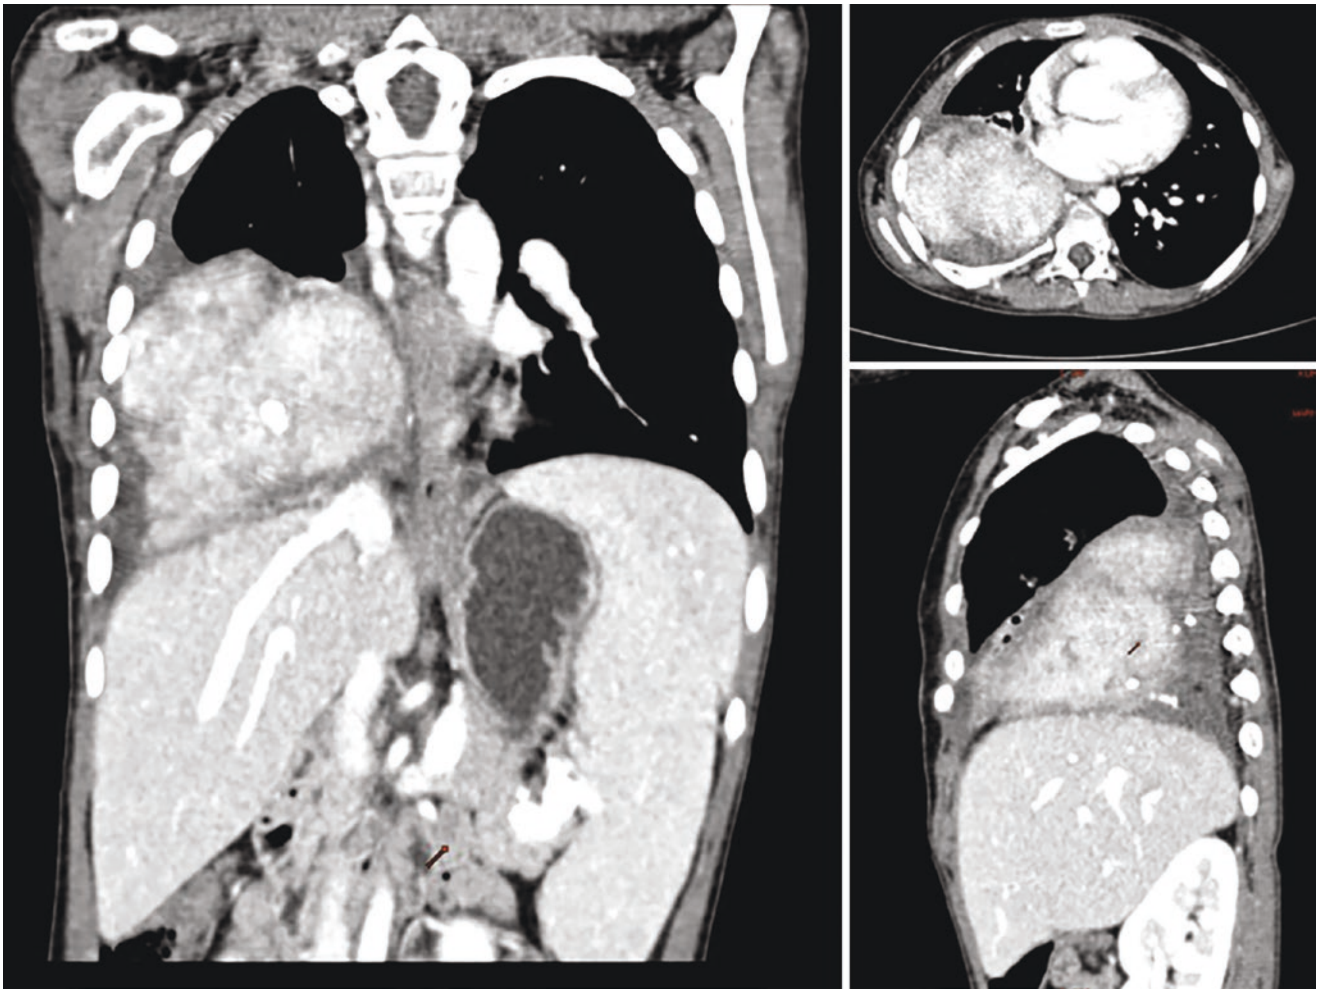

Fig. 4 CT thorax showing a completely solid lesion arising from the pleural surface suggestive of pleuropulmonary blastoma

2.4 Pancreatoblastoma

2.4.1 Epidemiology

Historically termed as "infantile carcinoma of the pancreas, pancreatoblastoma is the most common pancreatic tumor in young children and accounts for 10%–20% of all childhood pancreatic tumors." The clinicopathological features and treatment approaches mirror that of hepatoblastoma as both have an identical age group, common association with Beckwith–Weidman syndrome and FAP, common molecular drivers (CTNNB1 and IGF2 gene mutations), AFP as a tumor marker, similar chemotherapy backbone (cisplatin and doxorubicin) and surgery being the mainstay of therapy [3]. The genesis of PB is though to be the fetal pancreatic acinar cell.

2.4.2 Clinical Features

Nearly half of the cases arise from the head of pancreas. Upper abdominal pain, epigastric mass and gastric outlet obstruction can be presenting symptoms.

A third of patients develop metastatic spread to liver (via the portal circulation), lungs (haematogenous spread) and lymph nodes (lymphtaic) a third of patients can develop distant metastases, chiefly lungs [6].

Paraneoplastic syndromes due to secretion of ADH and ACTH can rarely occur [37].

2.4.3 Diagnostic Work-up

- Blood work including liver function tests and serum AFP (to be correlated with age as per nomograms) [38]
- Regional imaging with CT/MRI abdomen
- Staging with CT Chest or PET/CT scan. Bone scintigraphy can be used to screen for bone mets in centres where PET/CT is unavailable

2.4.4 Treatment

Akin to ACC, pancreatoblastoma is a surgical tumor with complete surgical excision the cornerstone of treatment. As most of the tumors involve the head of the pancreas, a Whipple procedure is the surgery of choice.

Because of its rarity, guidelines on chemotherapy are derived from collaborative groups. PB was in fact the first tumor to be reviewed by the EXPeRT committee to analyze the clinical findings and therapy outcomes [6].

For locally advanced and metastatic tumors, chemotherapy regimen consisting of cisplatin and doxorubicin is recommended (similar to PLADO regimen in hepatoblastoma). In a cohort of 20 patients, 18 received chemotherapy with a response rate of 73% and 5-year EFS/OS of 58.8%/79.4% [6].

2.5 Desmoplastic Small Round Cell Tumor (DSRCT)

2.5.1 Epidemiology

Overall, soft tissue sarcomas represent only 10% of all childhood cancers, of which DSRCT is the rarest member. Relatively new to the sarcoma family, it was first described by Gerald and Rosai at Memorial Sloan Kettering in 1989 [39], 9 years before its canonical EWS-WT1, t(11;22)(p13:q12) was identified [40]. DSRCT is a small blue round cell tumor that arises in the peritoneal cavity. It affects young patients in their second and third decade of life, with a striking male predilection.

2.5.2 Clinical Features

DSRCT is an aggressive sarcoma arising from the peritoneum and characterized by multifocal tumors and extensive locoregional spread [41].

Vague abdominal discomfort, pain and discomfort are the most common presenting symptoms. Coating of peritoneum with these tumors causes impaired resorption of peritoneal fluid leading to ascites. Tumor dissemination occurs most commonly to the liver and rarely to pleura, lungs, paratesticular region and supraclavicular lymph nodes [41].

2.5.3 Diagnostic Work-up

- Blood work including complete blood count and CA-125
- Biopsy of the lesion with demonstration of the characteristic translocation (EWS-WT1) is 100% confirmatory of DSRCT. Microscopy demonstrates nests of small blue round cells separated by desmoplastic stroma. Immunohistochemistry shows positivity for epithelial (keratin, EMA), mesenchymal (vimentin) and neural (NSE, CD99) markers. WT1 is positive in about 80%–90% DSRCT.
- Imaging: CT (computed tomography) scan of the thorax, abdomen and pelvis. Alternatively PET (positron emission tomography) -CT scan is increasingly being used as a single investigation for both local assessment and screening for distant metastasis and it is associated with a low negative predictive value.
- Two staging symptoms have been described: Peritoneal Cancer Index and MDACC staging system. The MDACC staging system is as below [41]:
  - Stage 1: Limited disease, localized to one or two sites in the abdomen or one site elsewhere.
  - Stage 2: Patients with any amount of extensive peritoneal disease;
  - Stage 3: Patients with liver metastasis and peritoneal disease
  - Stage 4: Patients with peritoneal and liver disease, as well as disease outside the abdominal cavity, including in the lymph nodes.

2.5.4 Treatment

DSRCT is treated on a multimodality regimen employing an Ewing sarcoma-like chemotherapy backbone with local therapy ranging from cytoreductive surgery, HiPEC (hyperthermic peritoneal perfusion), whole abdominal radiotherapy to stereotactic radiosurgery.

Chemotherapy regimens that have been tried are as follows*:

1. P6 regimen [42] (alternating courses of high-dose cyclophosphamide, doxorubicin, vincristine and ifosfamide-etoposide); response rate: 100%
2. Interval compressed VDC/IE [43] (Ewing sarcoma regimen); response rate: 68.4%
3. Standard VDC/IE; response rate: 48.2%
4. Addition of irinotecan-temsirolimus to the VDC/IE compressed regimen; response rate: 50% [44]

* please note that %s indicate the response rate. Despite aggressive and multimodality therapy, DSRCT is a group of tumors associated with dismal survival rates, with 5-year OS at 30%–40%.

2.6 Undifferentiated Embryonal Sarcoma of the Liver

2.6.1 Epidemiology

Historically termed as malignant mesenchymoma and fibromyxoma of the liver, undifferentiated embryonal sarcoma of liver (UESL) was known by its current term in 1978 [45]. An aggressive sarcoma, it is the third most common pediatric liver tumor (after hepatoblastoma and hepatocellular carcinoma) with a median age of 10.5 years and equal gender predilection [46].

2.6.2 Clinical Features

UESL presents as an abdominal lump and nonspecific symptoms of fever, nausea and anorexia in older children. Rhabdomyosarcoma (RMS) of the biliary tract is a close differential and several clinicopathological differences have been

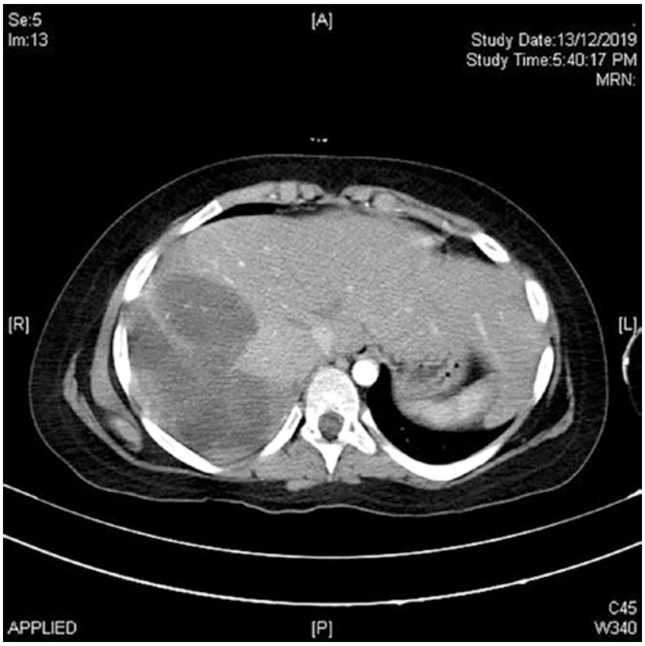

Fig. 5 Atypical lesion of UESL; a cystic lesion with necrosis within, arising from right lobe of the liver

described between the two [46]. An older age of onset, absence of obstructive symptoms like jaundice at presentation and location in the right lobe characterize UESL more than RMS (Fig. 5). Additionally, on IHC, UESL stains negative for myogenin and myoD1. Cytogenetic evidence of chromosomal breakpoint at 19q(13.4) (also present in hepatic mesenchymal hamartoma) also aids in differentiating this from RMS. An ultrasonography demonstrates the cystic/mixed nature of the swelling.

2.6.3 Treatment and Outcomes

Surgical resection with or without chemotherapy is the choice of treatment in children. It is a chemosensitive tumor with alkylating-based regimen with or without anthracyclines forming the front-line therapy with carboplatin-etoposide as second-line therapy [47]. The 5-year overall survival is quite impressive and ranges between 72%–80% [47–49].

Despite its chemosensitivity, inability to achieve complete clearance of all tumor sites portends a poor prognosis. Orthotopic liver transplantation is a viable method of attaining local control in tumors, which would otherwise be unresectable [49].

Childhood and Adolescent Extracranial Germ Cell Tumors

Subramaniam Ramanathan and Maya Prasad

Abbreviations

AFP	Alpha-fetoprotein
AUC	Area under the curve
BEP	Bleomycin, etoposide and cisplatin (weekly bleomycin)
BIP	Bleomycin-induced pneumonitis
GCT	Germ-cell tumor
GFR	Glomerular filtration rate
HBCR	Hospital-based cancer registry
LDH	Lactate dehydrogenase
PEb	CISPLATIN, Etoposide, bleomycin (3-weekly bleomycin)
PGC	Primordial germ cell
RPLN	Retroperitoneal lymph node
RT	Radiation therapy
SCT	Sacrococcygeal tumor
β-HCG	Beta-human chorionic gonadotropin

1 Introduction

Germ-cell tumors (GCTs) are a rare, heterogeneous group of tumors arising from the primordial germ cells with a favorable survival, even in advanced stages. GCTs arise from molecular defects in primordial germ cells (PGCs) in the gonads. PGCs are totipotent in nature with an ability to differentiate to all three germ layers and extraembryonic tissues. Migration of PGCs from the yolk sac through the midline of the developing embryo happens at around third week which is governed by strict temporospatial expression of chemomediators like CXRC4 and CXCL12 [1]. Aberrant migration of these cells along their course explains the proclivity for extragonadal GCTs to occur in midline.

Multidisciplinary approach over a backbone of platinum-based chemotherapy has dramatically improved survival in pediatric extracranial germ-cell tumors. Recent efforts to achieve better outcomes are directed toward harmonization of risk stratification across various groups and reducing therapy in favorable risk groups to minimize treatment related toxicity.

2 Incidence and Epidemiology

Extracranial germ-cell tumors constitute about 3% of all the pediatric malignancies (age <15 years) and display a bimodal distribution [2]. This increases to about 14% at onset of puberty (15–19 years), making it the most common solid tumor, and the second most common malignancy after Hodgkin's lymphoma in adolescents of both genders [3]. Data from the SEER database suggests the age-adjusted incidence of extracranial germ-cell tumors in the United States to be 11.7 per million in boys and 6.7 per million in girls [4]. Data on incidence in India is lacking because of poor reporting and inaccurate staging. A recent hospital-based cancer registry (HBCR) reported the incidence of GCTs to be 1.6–3.6% in boys and 0.8–4.5% in girls among all childhood cancers [5]. A single-center cross-sectional review in Indian children reports the annual incidence of GCTs to be 11.4% among all pediatric solid tumors with an equal gender predilection. The gonadal tumors were commonly seen in females above 10 years of age, while the extragonadal tumors were more commonly seen in children <4 years [6].

A number of clinical risk factors do exist (some with conflicting evidence) like presence of cryptorchidism, maternal estrogen levels during pregnancy, parental lifestyle, higher birth weight but none of the studies have been adequately powered to be assigned an attributable risk [7]. In adults, a positive family history is elicitable in 1–3% of cases of GCT [8, 9]. Such an association has not been found in pediatric GCTs [7].

3 Clinical Presentation

Clinical presentation including signs and symptoms of GCTs are dictated by its location (extragonadal or gonadal) and regional extent. Distant metastatic disease is usually present in 20% with lungs being the most common site [3]. The clinical presentation of GCTs across all locations is summarized in Table 1.

Testicular GCTs are usually painless and presence of pain usually indicates benign etiologies like epididymo-orchitis or torsion. Ovarian GCTs however are associated with pain in 85% cases. Extragonadal GCTs depending on the site can have varied presentations depending on its site. Extragonadal GCTs can occur in sacrococcygeal, retroperitoneal, mediastinal and other atypical locations.

Sacrococcygeal tumors (SCTs), much more common in females than males, present in early infancy until about 4 years of age, with a varying histological subtype (teratomas in the perinatal period and malignant GCTs in early childhood). Depending on the extent of internalization or externalization (with respect to the pelvic cavity) of the primary lesion, Altman classified SCTs from Type I-IV; Type I being completely external and Type IV being entirely internal (Fig. 1) [10]. Nearly 18% of SCTs in this cohort had associated congenital anomalies. Presacral tumors that are predominately internal present later in infancy through 4 years of age. Usual presenting symptoms of an internal lesion are either constipation or a buttock/abdominal mass; probability is quite high that these lesions are malignant [11]. Indian studies, albeit in small populations have shown a similar distribution [12, 13].

Table 1 Clinical presentation of germ-cell tumors (GCTs)

Testicular	Ovarian	Extragonadal
• Presents as a unilateral painless swelling. • Late presentation in developing countries can present as enlarged retroperitoneal lymph nodal mass in the abdomen • *Differentials* include: Paratesticular rhabdomyosarcoma, leukemic infiltration of the testis • Presence of pain indicates acute benign etiologies like torsion testis or epididymo-orchitis • *Children < 4 years:* Yolk sac tumors and immature teratomas are more common • *Children > 4 years:* Seminomas and mixed malignant GCTs are more seen	• Palpable abdominopelvic mass with abdominal pain in 85% patients • Rare accompanying clinical features include fever (10%), vaginal bleeding (10%) and isosexual precocity related to elevated beta-HCG • Unlike testicular tumors, histological subtype does not have any age correlation • *Differentials* include: Monodermal tumors (carcinomas), sarcomas, PNET • Rarely, Burkitt lymphoma can present as bilateral ovarian masses, bowel thickening and ascites	• *Sacrococcygeal:* Swelling over the back near the natal cleft with internal extension into the pelvis depending on subtype • *Mediastinal:* Anterior mediastinal mass with features of superior mediastinal syndrome in advanced cases • *Retroperitoneal:* Abdominal swelling with mass effect on adjacent organs with associated obstructive uropathy. Large masses can impinge on diaphragm causing respiratory distress • *Rare sites:* Vagina, orbit, adrenal • *Intracranial GCTs:* GCTs can occur in intracranial location also, most commonly in the pineal region; clinical presentation and management of intracranial GCTs have been dealt elsewhere

Mediastinal GCT in an adolescent male could be the presenting feature of Klinefelter syndrome. Lymphoma/T-cell leukemia often presents with anterior mediastinal masses; short history, presence of effusion and negative tumor markers help in differentiating this more common condition from mediastinal GCTs. In a COG study on malignant mediastinal GCTs, younger patients presented with respiratory complaints (mostly teratomas) while older children had chest pain, precocious puberty and facial fullness [14], which also contained more yolk sac elements.

4 Evaluation and Work-Up

4.1 History and Clinical Examination

4.1.1 Tumor Markers

Alpha-fetoprotein (AFP), a glycoprotein synthesized in the fetal liver and yolk sac, is elevated in about 70% nongerminomatous GCTs. Even immature teratomas can have elevated AFP because of microscopic yolk sac elements. Age-adjusted values as per nomograms (Table 2) assist in identifying pathological elevation of AFP [15]. Childhood neoplastic conditions apart from GCTs that cause elevated AFP of varying magnitude include hepatoblastoma, hepatocellular carcinoma and hemangioendothelioma. β-Human chorionic gonadotropin (β-HCG), a peptide hormone synthesized by the developing embryo soon after conception and later by the placenta (syncytiotrophoblast), is seen to be elevated in tumors arising from extraembryonic tissues, like choriocarcinoma and rarely in dysgerminoma/seminoma. Raised β-HCG can also be seen in hepatoblastoma, neuroendocrine tumors, gestational trophoblastic diseases and pregnancy [16]. Other tumor markers like inhibin and lactate dehydrogenase (LDH) can be elevated in granulosa cell tumors and dysgerminomas, respectively. While the prognostic significance of elevated tumor markers (especially AFP) at presentation and its serial decline in adult population is well established [17, 18] studies in pediatric GCTs have failed to replicate this observation [19]. Lack of favorable decline in AFP however has been used as a criterion for upstaging the completely resected gonadal GCTs from Stage I to Stage II in the COG staging system (described later).

Table 2 Normal levels of serum alpha-fetoprotein [15]

Age (months)	Mean αFP (ng/mL)	αFP 95% range (ng/mL)
0	41,687	9120–190,546
1	36,391	7943–165,959
2	31,769	6950–144,544
3	27,733	6026–125,893
4	24,210	5297–109,648
5	21,135	4624–96,605
6	18,450	4037–84,334
7	16,107	3524–73,621
8–14	9333	1480–58,887
15–21	3631	575–22,910
22–28	1396	316–6310
29–45	417	30–5754
46–60	178	16–1995
61–90	80	6–1045
91–120	36	3–417
121–150	20	2–216
151–180	13	125–129
181–720	8	0.8–87

4.1.2 Imaging

It is a radiological evaluation of the locoregional extent of disease (ultrasound for testicular lesions and MRI/CT for other sites; noncontrast CT of chest). While presence of fat and bony elements defines teratomas, it is rare in seminoma/dysgerminoma which are more uniformly lobulated masses with interdividing septae. Secretory GCTs (yolk sac tumors, mixed GCTs and choriocarcinomas) are characterized by presence of irregular margins, necrosis and occasionally hemorrhage. Clinical symptoms must prompt bone-scan for evaluating metastases if any. MRI of brain should be obtained in all cases of choriocarcinoma [3].

4.2 Histopathological Examination

Broadly, GCTs are classified into teratomas (immature and mature) and malignant GCTs (yolk sac tumor, germinoma, embryonal carcinoma and choriocarcinoma).

Teratomas are well-demarcated solid-cystic masses, which harbor elements from all three germ layers, viz., hair, fat, teeth, sebaceous and keratinous material. While mature teratomas contain well-differentiated elements, immature teratomas show presence of fetal/embryonal counterparts of the same, most commonly neuroectodermal tissue and cellular mesenchyme. On the basis of immature neuroectodermal tissue, Norris et al. classified these into Grade 1–3 (Grade 1: rare foci ≤1/low power field; Grade 2: multiple foci ≤3/low power field; Grade 3: ≥4/low power field) [20]. Unlike in adults, prognostic relevance of grading on outcomes (inferior outcome with increasing grade) has not been described in children [21, 22].

Among the malignant GCTs, yolk sac tumor/endodermal sinus tumors are the most common variety. These are characterized by round to polygonal cells with a high nuclear-to-cytoplasmic ratio, with presence of Schiller-Duval bodies (sinusoidal structures with a central vascular core and a peripheral rim of flattened tumor cells). On IHC, they stain positive for AFP, cytokeratin, glypican-3 and Lin-28.

Seminoma/dysgerminoma is an umbrella term used for similar looking tumors in testis and ovary respectively. Analogous tumors in extrangonadal/intracranial locations are termed as germinomas. They are characterized by sheets of large, monotonous cells with prominent nucleoli, separated by fibrovascular septae with lymphoplasmacytic infiltrate. On IHC, they stain positive for Lin-28, PLAP and c-kit but are negative for AFP/β-HCG.

Isolated embryonal carcinomas are rare in children and usually one of the components in a malignant mixed germ-cell tumor. They are characteristically positive for CD-30 on IHC and stain negative for EMA, CEA and vimentin.

In practice, radiologically compatible lesions with unequivocal elevation of tumor markers obviate the need for a biopsy prior to starting definitive chemotherapy. In such inoperable cases, a second look surgery can be performed after 2–4 cycles of neoadjuvant chemotherapy, with the post-operative specimen revealing mostly mature teratomatous elements.

4.2.1 Role of Micro-RNAs [23]

Although tumor markers provide a practical and effective method of both diagnosis and monitoring during treatment of GCTs, their utility is limited to secretory GCTs. Nonsecretory GCTs (NSGCTs, embryonal carcinomas and teratomas) hence demand novel biomarkers.

Micro-RNAs are short, nonprotein-coding RNAs that are released into the bloodstream from cancer cells (within exosomes). Micro-RNAs from two “clusters,” miR-371–373 and miR-302–367, are overexpressed in all malignant GCTs, regardless of age, site and histopathological subtype [23]. Because they remain undegraded in circulation, micro-RNAs might be useful in diagnosis, disease monitoring and prognostication of malignant GCTs.

5 Principles of Management

Following the above investigations, GCTs are staged and risk-stratified for treatment. Universally the COG staging is employed in children; this is a surgical staging which varies as per site of primary tumor (Table 3) [24]. While the staging has strong surgical principles, a key feature is the incorporation of AFP measurement into this staging system. The importance of evaluating AFP before starting any treatment and its serial measurement (has bearing on staging) cannot be overemphasized. Although the risk strata widely vary across different study groups, the present philosophy is to *decrease therapy in favorable risk groups* to minimize long-term toxicity and *intensify therapy in advanced stage disease*. A recent review succinctly puts forth the notion of a more functional classification [3], where low-risk tumors can only be observed after surgical resection, intermediate-risk tumors can be given less chemotherapy while still achieving a comparable outcome and high-risk tumors be treated with newer effective regimens. To systematize the risk stratification taking into account all possible prognostic factors in pediatric GCTs, data from seven GCT trials were pooled, based on which a new evidence-based risk stratification for pediatric GCTs was formed. The analysis identified a group of patients aged ≥11 years with either stage III to IV extragonadal tumors or stage IV ovarian tumors with an inferior survival. In addition, Stage III/IV testicular tumors in children ≥11 years with IGCCC (International Germ Cell Consensus Classification)—intermediate/poor risk were also identified as poor performers. All these groups are now stratified as Poor Risk in the new risk stratification. The Standard Risk group has been subdivided into Standard Risk—1 and Standard Risk 2 based on age as previously mentioned [19]. The current multicenter AGCT1531 trial is employing this contemporary risk stratification [25].

5.1 Surgical Management [26]

5.1.1 Surgical Management of Testicular Tumors

High-inguinal radical orchiectomy (ligation of all cord structures at the level of the internal inguinal ring) should be the surgical approach for a scrotal tumor. In rare occasions, such as a prepubertal boy with a proven teratoma with no biochemical/radiological disease elsewhere, focal enucleation is adequate. In the event of scrotal violation, patient continues to be in stage I if tumor capsule remains intact and tumor markers decline appropriately. If the cord structures show evidence of tumor spread, the patient should be upstaged to stage II. A trans-scrotal biopsy however warrants a completion orchiectomy following upstaging to Stage II. Hemiscrotectomy is not required. Routine retroperitoneal lymph node (RPLN) dissection is not required. While children with RPLN of size >2 cm on baseline imaging and RPLN <2 cm coupled with elevated AFP are stratified as Stage III, children with presence of RPLN measuring 1–2 cm with normal AFP warrant a repeat imaging ±RPLN biopsy for appropriate staging.

5.1.2 Surgical Management of Ovarian Tumors [27]

Open surgical resection is recommended. The following guidelines are advocated by COG: (a) collection of peritoneal fluid or washings for cytology (b) examination of peritoneal surfaces with biopsy of any abnormal areas; (c) palpation of retroperitoneal lymph nodes; biopsy only if abnormal (firm or enlarged); (d) inspection of omentum; biopsy only if abnormal; (e) palpation/inspection of opposite ovary; biopsy only if abnormal; (f) Complete resection of involved ovary intact (no capsule entry on field) with sparing of fallopian tube if not involved. For bilateral ovarian tumors, wedge biopsy of one should be performed and the patient should have second look surgery after neoadjuvant chemotherapy, which would preferably be a fertility preserving surgery.

Table 3 COG staging of pediatric GCTs [24]

Testicular	
I	(1) Tumor limited to testis (testes) with negative microscopic margins, completely resected by high inguinal orchiectomy; (2) Tumor capsule cannot have been violated by needle biopsy, incisional biopsy or tumor rupture. Patients who have undergone scrotal orchiectomy without violation of the tumor capsule and with removal of the spermatic cord to the level of the internal ring are stage I. Patients who have undergone excisional biopsy for frozen section analysis with complete orchiectomy and cord excision at the same operation can be designated stage I. (3) No clinical, radiographic or histologic evidence of disease beyond the testes. (4) Lymph nodes all <1 cm maximum short-axis diameter on multiplanar imaging
II	(1) complete orchiectomy with violation of the tumor capsule in situ (includes preoperative needle biopsy and incisional biopsy or intraoperative tumor capsule rupture); (2) microscopic disease in scrotum or high in spermatic cord (<5 cm from proximal end). Failure of tumor markers to normalize or decrease with an appropriate half-life; (3) lymph nodes negative
III	(1) retroperitoneal lymph node involvement, but no visceral or extra-abdominal involvement; (2) lymph nodes ≥2 cm or lymph nodes >1 cm but <2 cm on short axis by multiplanar imaging CT that fail to resolve on reimaging at 4–6 weeks
IV	(1) distant metastases, including liver, lung, bone and brain
Ovarian	
I	(1) ovarian tumor removed without violation of the tumor capsule; (2) no evidence of partial or complete capsular penetration; (3) peritoneal cytology negative for malignant cells; (4) peritoneal surfaces and omentum documented to be free of disease in operative note or biopsied with negative histology if abnormal in appearance; (5) lymph nodes all <1 cm by short-axis diameter on multiplanar imaging or biopsy proven negative
II	(1) ovarian tumor completely removed but with preoperative biopsy, violation of tumor capsule *in situ* or presence of partial or complete capsule penetration at histology; (2) tumor >10 cm removed laparoscopically; (3) tumor morcellated for removal so that capsule cannot be assessed for penetration; (4) peritoneal cytology must be negative for malignant cells; (5) lymph nodes, peritoneal surfaces and omentum documented to be free of disease in operative note or biopsied with negative histology if abnormal in appearance
III	(1) lymph nodes ≥2 cm or lymph nodes >1 cm but <2 cm on short axis by multiplanar imaging CT that fail to resolve on reimaging at 4–6 weeks; (2) ovarian tumor biopsied or removal with gross residual; (3) positive peritoneal fluid cytology for malignant cells, including immature teratoma; (4) lymph nodes positive for malignant cells, including immature teratoma; (5) peritoneal implants positive for malignant cells, including immature teratoma
IIIX	Patients otherwise stage I or II by COG criteria but with the following: (1) failure to collect peritoneal cytology; (2) failure to biopsy lymph nodes >1 cm on short axis by multiplanar imaging; (3) failure to sample abnormal peritoneal surfaces or omentum; or (4) delayed completion of surgical staging at a second procedure for patients who had only oophorectomy at first procedure
IV	(1) metastatic disease to the parenchyma of the liver (surface implants are stage III) or metastases outside the peritoneal cavity to any other viscera (bone, lung or brain) and pleural fluid with positive cytology
Extragonadal	
I	(1) complete resection at any site, including coccygectomy for sacrococcygeal site; (2) must have negative tumor margins and intact capsule; (3) for any tumors involving abdominal cavity or retroperitoneum, peritoneal fluid or washings must be done for cytology and be negative for malignant cells; (4) lymph nodes ≤1 cm by imaging of abdomen, pelvis and chest
II	(1) microscopic residual disease; (2) gross-total resection with preoperative biopsy, intraoperative biopsy, microscopic residual disease or pathologic evidence of capsular disruption; (3) lymph nodes negative by abdomen, pelvic and chest imaging. Peritoneal fluid negative
III	(1) Gross residual disease or biopsy only; (2) lymph nodes positive with tumor resection. Lymph nodes ≥2 cm or lymph nodes >1 cm but <2 cm on short axis by multiplanar imaging CT that fail to resolve on reimaging at 4–6 weeks
IV	Distant metastases, including liver, lung, bone and brain

5.1.3 Surgical Management of Sacrococcygeal Tumors

The behavior of SCTs differs by age; 90% of neonatal SCTs are benign with the proportion of malignant tumors increases with age. Despite this difference, the surgical objective is to achieve a complete excision (including en-bloc resection of coccyx) with negative margins [27]. Because the tumor configuration beyond the neonatal period is more likely to have an internal component close to pelvic structures, upfront resection must be gauged against possible long-term gastrointestinal, genitourinary and neurological sequelae [28]. Literature also suggests to define the extent of neurologic, gastrointestinal and genitourinary dysfunction before any intervention so as to categorize any impairment of function at baseline and after surgery [29]. Also, delayed resection in SCTs did not adversely impact the outcome in published studies [30, 31]. In light of these observations, an initial biopsy followed by elective surgery after 2–4 cycles of neoadjuvant chemotherapy can be considered.

5.2 Surgical Management of Mediastinal Tumors

Large mediastinal masses with a precarious airway must undergo surgical resection only after a proper risk assessment for anesthesia [26]. In a German cohort of 23 children with mediastinal GCTs, delayed resection was reported to increase the odds of complete resection of primary tumor with superior outcomes (EFS: 94% vs. 42%); an observation which was noted with SCTs as well [32]. Hence, in a secretory GCT, it would be well-judged to attempt a delayed resection following neoadjuvant chemotherapy. Approaches via lateral thoracotomy or median sternotomy are acceptable, and should include adherent non vital structures such as the thymus and pericardium with evaluation of regional lymph nodes when possible [11].

5.3 Chemotherapeutic Approaches

5.3.1 Clinicolaboratory Work-Up (Summarized in Table 4)

Chemotherapy

Platinum-based therapies have been the backbone of chemotherapy regimens for GCTs after a seminal study incorporating vinblastine, cisplatin and bleomycin [33]. Patients on this study had a survival rate of 64% and overall response rate of 100%. The present-day combination chemotherapy of bleomycin, etoposide and cisplatin (BEP) was the result of a randomized controlled trial with BEP arm having a better response rate in those with high tumor volume with fewer toxicities (neuromuscular) as compared to the vinblastine arm [34].

Table 4 Prechemotherapy evaluation and monitoring posttreatment

Prechemotherapy evaluation:

- Hemogram, renal function tests, liver function tests prior to every cycle of therapy
- Serial monitoring of tumor markers prior to every cycle
- Baseline measurements of glomerular filtration rate (GFR), pulmonary function tests (PFTs + DL-CO) and audiometry, which need to be reassessed mid-and end of-chemotherapy
- Although not standard in pediatric patients, oocyte preservation and sperm cryopreservation can be offered to postpubertal patients because of a small risk of infertility
- Clinical and radiological assessment should be performed after 2–4 cycles of chemotherapy

Surveillance postcompletion of therapy:

- Clinical evaluation at every follow-up visit
- Tumor markers (at the author's institution, tumor marker of interest is done at 3 monthly intervals for the first 12 months, 6 monthly intervals during the second year and yearly thereafter)
- Imaging of the primary tumor site is generally done if the tumor markers are elevated. In cases of teratomas however, serial ultrasound abdomen (in case of pelvic or abdominal tumors) or chest radiographs (in mediastinal primary) can be done.
- Serum electrolytes at every follow-up visit to look for tubular dysfunction.

Audiometry for only in symptomatic patients

Chemotherapy for pediatric GCT was adapted from these regimens by North American groups in their studies POG-9048 (low stage gonadal tumors) and POG-9049 (high-risk protocol) [35, 36]. Owing to concerns with bleomycin-related long-term pulmonary toxicity, the dose of bleomycin was reduced from 3 doses/cycle to 1 dose/cycle on day -1 alone, and termed PEb. PEb comprises Bleomycin 15 U/m^2 intravenous (IV) on day 1, Etoposide 100 mg/m^2/day IV on days 1–5 and Cisplatin 20 mg/m^2/day IV on days 1–5. Stage I gonadal tumors in boys were managed with surgical resection alone, and chemotherapy was given to other low stage gonadal (comprising of relapsed Stage I testicular tumors and Stage I/II ovarian tumors) tumors, yielding survival rates of 95% to 100% in this group of tumors. A randomized trial to assess the efficacy of high-dose cisplatin (HDPEB—200 mg/m^2/cycle) compared to standard-dose cisplatin (PEB—100 mg/m^2) in high-risk GCTs did not show a significant difference in 6-year OS between HDPEB and PEB (92% vs. 86%), although there was evidence of an increase in 6-year EFS among patients receiving HDPEB (89.6% ± 3.6% vs. 80.5 ± 4.8%, $p = 0.03$). Toxicity was much higher in the HDPEB arm with 6/7 (86%) of all deaths in HD PEB arm and 67% children requiring assisted hearing devices, thus limiting the use of this regimen.

Subsequent COG studies adopted a watch-and-wait policy for low-risk patients, reserving chemotherapy for those who

Table 5 Summary of treatment (chemotherapy) and outcomes of GCTs in the United States and United Kingdom [29, 39]

	United States (POG 9048, 9049, AGCT0132)			United Kingdom (GC – II)		
	Therapy	Number	6-year EFS/OS	Therapy	Number	4-year EFS/OS
Testicular						
Stage I	Observation	63	78.5%/100%	Observation	51[a]	78%/100%
Stage II–IV	4 PEb vs. HDPEb	60 (30/30)	89.8%/93.3%	JEb[b]	12	n = 137 87.8%/90.9%
Ovarian						
Stage I	Observation	25	52%/96% (*4 years*)	JEb[b]	54[c]	
Stage II–IV	4 PEb vs. HDPEb	74 (37/37)	94.5%/97.3%			
Extragonadal						
Stage I–IV	4 PEb vs. HDPEb	165 (82/83)	79.0%/83.4%	JEb[b]	67[d]	

[a] 11 children who relapsed on observation were given JEb chemotherapy

[b] Chemotherapy was given until remission plus 2 more

[c] 6 children were treated with surgery alone

[d] 1 child with thoracic stage I was treated with surgery alone

fail observation after surgery and assessed efficacy of 3 courses of PEb in a dose-intense fashion for intermediate-risk tumors. Among the stage I ovarian tumors, 52% were treated with surgery alone and 11/12 patients who had a relapse were successfully salvaged with an OS of 96%. Testicular stage I tumors had an excellent OS of 100% [37, 38]. Decrease in number of courses of PEb in intermediate-risk tumors led to an EFS of 89% but was less than an expected EFS of 92%, hence 4 cycles continue to remain the present standard treatment regimen for intermediate-risk patients.

GCT trials (GC-I, GC-II) in the United Kingdom utilized a carboplatin-based chemotherapy backbone (JEb) [38, 39]. JEb consists of carboplatin on day 2 in at an area under the curve (AUC) of 7.9 (AUC formula: [6 × *uncorrected GFR*] + [15 × *surface area*]), equivalent to approximately 600 mg/m^2; etoposide 120 mg/m^2/day for days 1 through 3 (total dose 360 mg/m^2); and bleomycin 15 mg/m^2 on day 3. Notably, in the GCI–GCII trials, the dose of carboplatin was more dose-intense and of higher dose as compared to contemporary protocols, and EFS and OS were comparable to that of COG studies which used cisplatin (Table 5), making carboplatin (at optimal dose intensity and frequency) a reasonable alternative to cisplatin due to ease of administration and favorable toxicity profile. The inferior outcomes that have been shown in adult GCT on carboplatin-based therapies are due to suboptimal dosing (AUC 3–5 versus AUC 7.9 or 350–500 mg/m^2), inadequate dose-intensity and a lower dose of other chemotherapy agents [40]. Data on head-to-head comparison of the efficacy and toxicity spectrum of cisplatin versus carboplatin in a randomized fashion at present is lacking [41]. A report of MaGIC consortium comparing the outcomes on GCTs treated on cisplatin or carboplatin by the COG and UKCCLG group found no significant difference in outcome observed overall or any subset of patients. Hence, there is parity in outcomes of pediatric GCTs treated with either cisplatin or carboplatin and little evidence to support choosing one over the other. For the final verdict, an international multicenter randomized controlled trial of carboplatin versus cisplatin, using pediatric carboplatin dosing and schedule, is underway [40]. Closer home, the outcomes are fairly comparable with a 5-yr-EFS/OS being between 60-70% and 70-80% respectively. Gonadal GCTs and low-interemdiate risk GCTs are associated with a better outcome. Regional challenges like late presentation, lack of AFP estimation prior to starting treatment, improper surgical techniques in the community (leading to stage migration and more intensive treatment), higher incidence of sepsis related deaths and treatment abandonment are hindrances to a better outcome [42–44].

Bleomycin in Pediatric GCTs

Bleomycin is an antitumor peptide which exerts its action by oxidative cleavage of DNA. Due to the serious (and often life-threatening) pulmonary toxicities of bleomycin, studies have focused on decreasing the cumulative doses of bleomycin. Adult and pediatric studies showed that reduction of therapy to two drugs (cisplatin + etoposide) and omitting bleomycin did not compromise outcome in selected cases [45, 46]. On German studies (MAKEI 83/86/89), following 2 deaths in children due to pulmonary fibrosis, bleomycin was entirely omitted from their subsequent protocol MAKEI/96 [47]. Most of the pediatric trials now use only a single dose of bleomycin (PEb/JEb) per cycle in their protocols. However, the current treatment algorithm in postpubertal GCT patients with poor risk (Table 4) recommends use of weekly bleomycin (i.e., 3 doses/cycle) [25].

5.4 Radiation Therapy

Indications of radiation therapy (RT) as a modality in upfront therapy of pediatric extracranial GCTs are fairly limited. In recurrent GCTs, radiotherapy is used when two lines of therapy are exhausted. German studies have reported the role of local RT to SCTs in unresectable cases; 3/5 patients who received RT >45 Gy were in continuous remission [48].

6 Toxicities of Treatment

Principal toxicities while on treatment are related to the chemotherapeutic agents in use and include myelotoxicity, ototoxicity, nephrotoxicity and pulmonary toxicity. The incidence of myelotoxicity is more with carboplatin-based regimens with major modification needed only in a small number of patients [49]. Otherwise, the incidence of ototoxicity is far less when compared to cisplatin-based chemotherapy.

To monitor these toxicities, baseline measurements of glomerular filtration rate (GFR), pulmonary function tests and audiometry, which need to be reassessed mid-and end of-chemotherapy. Although not standard in pediatric patients, oocyte preservation and sperm cryopreservation can be offered to postpubertal patients because of a small risk of infertility [11].

Details of late toxicities are outlined below in the section on late effects.

7 Late Effects

Survivors of childhood GCTs can potentially have 70 or more years of remaining life [41]. Therefore, identifying and tackling late effects assume importance. Because GCTs were not included in the Childhood Cancer Survivor Study, there is limited data on short-term and long-term data [50]. The St. Jude's database, a single-center experience with long-term effects in 73 survivors reports that nearly 50 (68%) had at least one long-term complication [51]. Several caveats like use of radiotherapy in frontline therapy and dose-intensive protocols incorporating alkylating agents (which are now archaic) in the above cohort restrict its wider extrapolation.

Toxicities of importance are outlined below:

- Ototoxicity: 60% of children treated with cisplatin develop permanent bilateral hearing loss. Platinum ototoxicity initially affects high-frequency hearing. High-frequency hearing loss causes difficulty in distinguishing high-frequency consonants that are critical for speech intelligibility, and it significantly impairs recognition of speech in the presence of background noise [52]. Although cisplatin is more ototoxic than other platinum-based drugs, carboplatin is also ototoxic, especially when delivered at myeloablative doses for autologous bone marrow transplantation or when administered in conjunction with osmotic opening of the blood–brain barrier [53]. A Phase-3 randomized trial on sodium thiosulfate (STS; an otoprotectant) in a heterogeneous population of children with solid tumors (16 GCTs in each arm) has demonstrated its efficacy, which needs to be validated in a larger cohort [54].
- Nephrotoxicity: Being a heavy metal, cisplatin remains in the body system for nearly 10 years after treatment. While glomerular function returns to 85% of pretreatment value within 4 years, the tubular function can stay impaired and persistent proximal tubular hypofunction has been reported in 20% patients [55].
- Pulmonary: The most serious complications of bleomycin are pneumonitis (bleomycin-induced pneumonitis–BIP) and pulmonary fibrosis which are estimated to be around 10% (adult studies) and can be life-threatening in up to 20% [56].
- Second malignancy: Adult studies have observed increased risk of secondary cancer occurring at 1% per year, with no plateau. Secondary leukemia after treatment with a conventional dose of etoposide does occur, but the low incidence does not alter the risk-to-benefit ratio of etoposide-based chemotherapy in germ-cell cancer [57].

8 Management of Recurrent/Relapsed Disease

Treatment options for recurrent pediatric GCTs are modeled on treatment options in adult clinical trials.

8.1 Surgery

Surgical resection in locally relapsed GCTs is still possible and patients achieve and sustain a durable remission if consolidated with salvage chemotherapy.

8.2 Chemotherapy

Limited data exist on optimal therapy for relapsed/refractory GCT. High-dose (HD) chemotherapy with autologous stem cell rescue has been explored as a treatment for adults with recurrent testicular GCTs. Pediatric data on HD chemotherapy is available only in small studies [58, 59]. Also, an appreciable percentage of patients fail to mobilize adequate hematopoietic stem cells (HSCs) numbers with granulocyte colony-stimulating factor (G-CSF) ± salvage chemotherapy, and require plerixafor for augmenting mobilization [60]. Experience from the author's centre (MP) on relapsed/refractory GCTs treated on conventional 2nd line chemotherapy regimens without autologous stem cell rescue showed that a small minority of patients with local relapses, gonadal primaries at baseline and with good biochemical response to 2 cycles (normalisation of tumor marker levels) could be salvaged with chemotherapy alone [61].

AGCT 0521 (COG Study) has used a combination chemotherapy of paclitaxel, ifosfamide and carboplatin (TIC) with a response rate of 44% (RECIST criteria and tumor marker decline) [62]. While TIC regimen can be considered as salvage in younger children (carboplatin instead of cisplatin) conventional dose chemotherapy with paclitaxel, ifosfamide and cisplatin (TIP) or HD chemotherapy with PI-CE (paclitaxel–ifosfamide followed by high-dose carboplatin–etoposide) are currently accepted standard options especially in adolescents. The AO31102 Alliance study (the TIGER trial; NCT02375204) will compare the survival of male patients randomized to conventional chemotherapy (TIP) versus PI-CE with stem-cell rescue [63].

9 Recent Advances

9.1 Role of miRNAs

As conventional tumor markers like AFP/beta-HCG are limited to specific tumor-subtypes within the larger cohort of malignant GCT, circulating miRNA have emerged as the next-generation tumor markers, with implications on treatment response and early detection of relapse [24].

9.2 Targeted Therapy

Because the pathogenesis of adult GCTs differ from pediatric GCTs, identifying and targeting the putative pathways for pediatric GCTs, viz., Wnt/β-catenin, BMP, notch and hedgehog should be the way forward.

10 How We Do It at TMC

Baseline Work-up

- **Diagnostic Investigations:** Serum alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (beta-CG).
- **Imaging:** CT/MRI of the primary site.
- **Pathology:** Biopsy is not mandatory except when the tumor markers are normal and/or clinicoradiological noncorrelation.
- **Staging:** CT chest/abdomen.

Staging

The TMC uses a risk-stratified approach as outlined in Table 6.

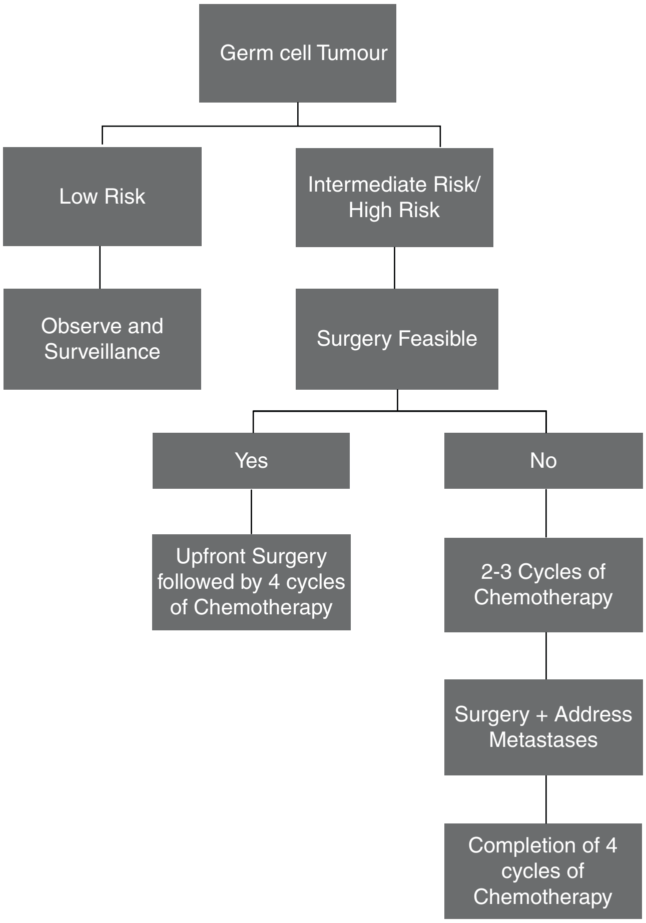
Chemotherapy Regimen

- Cisplatin: 33.3 mg/m^2/dose D1–D3.
- Etoposide: 167 mg/m^2/dose D1–D3.
- Bleomycin: 15 units/m^2/dose D1 only.
- Four cycles for intermediate/high-risk GCTs.
- No chemotherapy for low-risk GCTs.

Pediatric GCTs in TMC are managed as per an algorithmic approach (Fig. 2) [64].

Table 6 Risk-stratified therapy

Risk category	Stage/Site	Treatment
Low risk	Stage I testes, stage I ovary	Surgery alone and observe
Intermediate risk	Stage II–IV testes Stage II–III ovary Stage I–II extragonadal	Surgery and chemotherapy (4 cycles)
High risk	Stage IV ovary Stage III–IV Extragonadal	Surgery and chemotherapy (6 cycles)



Germ cell Tumour
Low Risk
Intermediate Risk/ High Risk
Observe and Surveillance
Surgery Feasible
Yes
No
Upfront Surgery followed by 4 cycles of Chemotherapy
2-3 Cycles of Chemotherapy
Surgery + Address Metastases
Completion of 4 cycles of Chemotherapy

Fig. 2 Tata Memorial Centre algorithmic approach to management [63]

Abbreviations

AFP	Alpha-fetoprotein
CECT	Contrast-enhanced abdominal computerized tomography
HACE	Hepatic artery chemoembolization
HB	Hepatoblastoma
HCC	Hepatocellular carcinoma
hCG	Human chorionic gonadotropin
hFLMPC	Human fetal liver multipotent progenitor cell
MRI	Magnetic resonance imaging
OLT	Orthotropic liver transplantation
SCU	Small cell undifferentiated
TACE	Transarterial chemoembolization

1 Introduction

Hepatoblastoma (HB) is the most common primary malignant liver neoplasm in children and is predominantly a tumor of infants and young children. Even so, it comprises only 1% of all pediatric malignancies [1]. Advances in multidisciplinary care, including those in imaging, chemotherapy, surgery and increasing use of liver transplantation, have led to improved outcomes in hepatoblastoma over the past few decades from 20% to 80%. These in turn have been spearheaded by collaborative groups across the globe, mainly Children's Oncology Group (COG), Liver Tumour Group of International Society of Pediatric Oncology (SIOPEL), the Japanese Pediatric Liver Tumor Group (JPLT) and German Pediatric Hematology Oncology Group (GPOH) [1].

2 Incidence and Epidemiology in India and Globally

The annual incidence of HB in the United States was reported to be 1.6 cases per 1 million children aged 18 years and less during 2002–2009 [2].

Although the exact incidence of HB in India is not known, hospital-based registries have reported hepatic tumors to be 0.5% to 4.5% of all childhood tumors in children less than 14 years [3].

Although most cases of HB are sporadic, there is a known association with constitutional genetic abnormalities such as Beckwith–Wiedemann syndrome familial adenomatous polyposis and trisomy 18 [4]. Hepatoblastoma is strongly associated with very low birth weight (VLBW; <1500 g), with odds ratio ranging from 9.5 to 69. The exact reason for this association is not known; gestational age does not appear to be a factor [4].

3 Clinical Presentation in India and Globally

HB is a tumor of very young children, and nearly all develop the tumor before 3 years of age; HB accounts for 90% of malignant liver tumors in children aged 4 years and younger [5]. Literature from India reports a median age at presentation of 7 to 34 months and a variable, but mostly higher incidence of pretext III and IV lesions. Outcomes are also variable, but mostly lower (5-year event-free survival of 67–80%) than in Western literature [6–12].

The common presentations are abdominal distension or abdominal mass, which could cause respiratory distress, discomfort and fatigue and loss of appetite. Less common presentations include tumor rupture and precocious puberty/virilization in tumors which secrete β-human chorionic gonadotropin (hCG).

4 Evaluation and Work-Up

4.1 Tumor Markers

Serum alpha-fetoprotein (AFP) is elevated in 90% of cases of hepatoblastoma, and S.AFP levels are important in diagnosis, prognosis and response to treatment. Variants such as small cell undifferentiated (SCU) hepatoblastoma are associated with low levels of S. AFP and dismal prognosis [13]. S. AFP levels are very high during the neonatal period and decrease consistently during the first year of life, reaching near-normal levels by 6 months of age (Table 1) [14]. The half-life of AFP is 5 to 7 days.

4.2 Radiology

Radiology is important in diagnosis, risk stratification and response assessment in hepatoblastoma. Although ultrasound of the liver is often the initial imaging procedure, the gold standard for diagnosis of hepatoblastoma is either a triphasic (noncontrast, arterial and venous phases) contrast-enhanced abdominal computerized tomography scan (CECT) or magnetic resonance imaging (MRI) with contrast agents such as gadoxetate disodium. Hepatoblastoma shows up on CT scans as a well-defined heterogeneous mass with lower attenuation compared to the normal liver. Areas of necrosis and hemorrhage as well as calcification may be seen. MRI is superior to CT in defining tumor margins, vessel involvement and adenopathy [15].

The extent of liver involvement and operability of tumor are defined using the Pre-Treatment Extent of Tumor or PRETEXT system [16–18]. The liver is divided into four parts called sectors, with the left lobe of the liver consisting of medial (Couinaud segment 4) and lateral sectors (segments 2 and 3) and right lobe consisting of anterior (segments 5 and 8) and posterior sectors (segments 6 and 7). Since Couinaud segment one corresponds with the caudate lobe, it is not included in this division. PRETEXT categories depend on the number of liver sectors free of tumor and describe the extent of tumor within the liver, while other factors such as venous or extrahepatic involvement or metastatic disease are denoted by "annotation factors" (Fig. 1) (Table 2). The PRETEXT system takes into account imaging features prior to start of treatment and has prognostic implications. PRETEXT was originally described by the Epithelial Liver Tumour group of Société Internationale d'Oncologie Pédiatrique (SIOPEL) in order to standardize imaging and risk stratification for its first study SIOPEL-1; it has subsequently been adopted by other major collaborative groups which conducted studies in hepatoblastoma such as the North American Children's Oncology Group (COG) and Japanese Study Group for Pediatric Liver Tumor (JPLT) [18]. PRETEXT classification following chemotherapy is denoted as POSTTEXT.

Table 1 Normal range of serum AFP values in normal-term babies[a]

Age (in Days)	Mean AFP (ng/mL)	AFP 95% Range (ng/mL)
0	41,687	9120–190,546
1	36,391	7943–165,959
2	31,769	6950–144,544

Table 2 PRETEXT Staging system [16]

Pretext group	Description
I	One section involved; three adjoining sections are tumor free
II	One or two sections involved; two adjoining sections are tumor free
III	Two or three sections involved; one adjoining section is tumor free
IV	Four sections involved
Annotation factors	
V	Venous involvement: Vascular involvement of the retrohepatic vena Cava or involvement of all three major hepatic veins (right, middle and left)
P	Portal involvement: Vascular involvement of the main portal vein and/or **both** right and left portal veins
E	Extrahepatic involvement of a contiguous structure such as the diaphragm, abdominal wall, stomach, colon, etc.
M	Distant metastatic disease (usually lungs, occasionally bone or brain)
R	Tumor rupture
N	Lymph node involvement
F	Multifocality
C	Caudate lobe involvement

4.3 Pathology

A biopsy may not be required in children aged 6 months to 3 years with clinical and radiological features typical of hepatoblastoma and raised serum AFP levels, or when radiological features are typical of infantile hemangioma or focal nodular hyperplasia.

Hepatoblastoma arises from precursors of hepatocytes B and also from less differentiated cells such as hepatic stem cells and human fetal liver multipotent progenitor cells (hFLMPCs). Morphology is most often a mixture of epithelial hepatocyte precursors, but can be heterogeneous. The most recent classification of hepatoblastoma has two groups—epithelial tumors (which includes fetal, embryonal, macrotrabecular, small-cell undifferentiated and cholangioblastic) and mixed tumors (stromal derivatives or teratoid) [19]. Tumors with well-differentiated "pure fetal" histology have an excellent prognosis, and completely resected tumors may not require adjuvant chemotherapy [20]. Tumors with small cell undifferentiated histology are seen in infants, present with low or normal levels of serum AFP (<100 ng/dL) and have features overlapping with rhabdoid tumor of liver, including dismal prognosis. The presence of even small foci of this histology warrants aggressive chemotherapy [21].

5 Principles of Management of Hepatoblastoma

There been tremendous improvement in the survival of children with hepatoblastoma from 20% to 80% over the past few decades [1]. This progress can be attributed to better understanding of surgical anatomy of liver, improved risk stratification, effective neoadjuvant chemotherapeutic agents and the availability of liver transplantation. These improvements have been largely due to multiple clinical trials by cooperative groups across the globe, which have adopted different treatment approaches but with similar outcomes. The European SIOPEL group advocates neoadjuvant chemotherapy followed by surgery in order to decrease tumor size and vascularity, improve resectability and address micrometastasis [1, 22]. In contrast, the North American COG recommends upfront surgery wherever possible, followed by chemotherapy. However, the PRETEXT classification as well as similar chemotherapy agents are common to both groups (as well as German Pediatric Hematology Oncology Group, GPOH and Japanese Pediatric Liver Tumor group, JPLT). These differing approaches have not been compared in a controlled manner. Recently, the Children's Hepatic Tumors International Collaboration (CHIC) merged data from eight collaborative hepatoblastoma trials to form a database of 1605 patients, which was then used to develop a global uniform risk stratification system, in turn laying the framework for the prospective international such as Paediatric Hepatic International Tumour Trial (PHITT) [23].

The SIOPEL group was formed in 1987 as an international (but Eurocentric) collaborative group of pediatric surgeons, oncologists, pathologists and radiologists who would focus on childhood liver tumors. There have been six trials conducted by this group which included patients with both hepatoblastoma (HB) and hepatocellular carcinoma (HCC) (Table 3).

Table 3 Summary of collaborative studies in hepatoblastoma

Study	Era and patients	Key messages
SIOP studies		
SIOPEL 1 [24–27]	1990–1994 153 HB; 40 HCC	PRETEXT staging Neoadjuvant chemotherapy (cisplatin–doxorubicin) followed by delayed surgery as standard of care Liver transplantation could increase resection rate
SIOPEL 2 [28]	1994–1998 135 HB; 20 HCC *pilot study of risk-stratified approach	Introduction of risk categories based on SIOPEL 1 results: Standard risk (SR) and high risk (HR) Risk-stratified treatment: Standard risk—cisplatin alone High risk—combination of cisplatin/doxorubin/carboplatin (Super PLADO) Efficacious in SR HB and acceptable toxicity in SR/HR
SIOPEL 3 [29, 30]	SIOPEL 3 SR-HB (1998–2005)—Prospective randomized trial on SR HB SIOPEL 3 HR-HB (1998–2004)—Prospective single-arm trial on HR HB 406 HB; 65 HCC	Standard risk—cisplatin alone as effective as PLADO and less toxic; High risk—combination of cisplatin/doxorubin/carboplatin (Super PLADO) significantly better than PLADO(cisplatin/ doxorubicin) Liver transplantation encouraged
SIOPEL 4 [31]	2005–2009 Prospective single-arm feasibility 62 HB	Intensified treatment of HR HB Neoadjuvant chemotherapy with weekly cisplatin, monthly doxorubicin followed by delayed surgery (carboplatin-doxorubicin, in those with poor response to NACT) Improved outcomes compared to historical controls
SIOPEL 5	2005–2009 Closed due to insufficient recruitment	Prospective single-arm trial devoted exclusively to the HCC
SIOPEL 6 [32]	2007–2017	Randomized controlled trial of cisplatin monotherapy with/without sodium thiosulfate Primary endpoint: To see if coadministration of sodium thiosulfate decreases hearing loss Interim analysis encouraging
SIOPEL RCN [33]		Risk-stratified treatment for resource-challenged nations (RCN) based on SIOPEL 3 study: SR—cisplatin monotherapy HR—1 cycle cisplatin and 5 cycles of PLADO
North American studies		
INT0098 [34]	1989–1992	No statistically significant differences in survival between cisplatin + fluorouracil + vincristine (C5V) or cisplatin + doxorubicin (PLADO) Cisplatin is the most active agent against HB
P9645 [35]	1999–2002 108 HB	Intensification of therapy by alternating cisplatin/carboplatin increased the risk of adverse outcome in unresectable/metastatic HB
COG AHEP 0731 [36]	Ongoing	Very-low-risk group: Surgery followed by observation Low-risk group: Surgery followed by C5V chemotherapy (cisplatin, fluorouracil, vincristine) Intermediate-risk group (regimen F): C5VD chemotherapy (cisplatin, fluorouracil, vincristine doxorubicin) High-risk group (regimen H): Upfront VIT chemotherapy (vincristine, irinotecan, temsirolimus) followed by C5VD chemotherapy alternating with VIT
German (GPOH) studies		
HB 89 [37]	1988–1992 37 HB	Advanced/metastatic HB Complete resection is essential for survival from advanced hepatoblastoma to prevent drug resistance Initial S.AFP values <100 ng/mL or > 1,000,000 ng/mL, slow decline of AFP, growth pattern of tumor within the liver (and vascular tumor invasion prognostic factors
HB 99 [38]	1999–2004 45 HB	Use of high-dose chemotherapy (CARBO/VP16) in HR HB
Japanese Paediatric Liver Tumour Group (JPLT) studies		
JPLT-1 [39]	1991–1999 145 HB	Stage I /II HB—cisplatin, pirarubicin (tetrahydropyranyl-adriamycin) low dose Stage IIIA, IIIB, IV HB: CDDP, pirarubicin higher dose Poor outcome for advanced HB
JPLT-2 [40]	1999–2010 212 HB	PRETEXT I: Primary resection followed by low doses of cisplatin-pirarubicin Others: Preoperative cisplatin-pirarubicin (CITA), followed by surgery and postoperative chemotherapy Salvage: Ifosfamide, pirarubicin, etoposide and carboplatin (ITEC) Metastatic diseases: High-dose chemotherapy with hematopoietic stem cell transplantation (SCT) Improved outcomes

6 Risk Stratification and Prognostic Factors

As with most other pediatric tumors, the treatment of hepatoblastoma is tailored to risk. Risk categories have been variously defined by major collaborative groups (see Table 4). Chemotherapy recommendations as per risk category are in Table 5.

Table 4 Risk stratification of hepatoblastoma [28]

	Very low risk	Standard/low risk	High risk
SIOPEL:		PRETEXT I, II or III	Any PRETEXT; V+, P+, E+, M+; SCU histology; AFP level < 100 ng/mL; tumor rupture
COG	PRETEXT I or II; well-differentiated fetal histology; primary resection at diagnosis	PRETEXT I or II of any histology with primary resection at diagnosis	Any PRETEXT with M+; AFP level < 100 ng/mL
Intermediate risk as per COG—PRETEXT II, III or IV unresectable at diagnosis; or V + C+, P+, E+; SCU histology small cell undifferentiated histology			

Table 5 Current recommendations for risk-stratified chemotherapy in hepatoblastoma [22, 28–30, 36, 38, 39]

Study group	Risk group	Neoadjuvant chemotherapy	Adjuvant chemotherapy
COG	Very low risk	NIL	NIL
	Low risk	NIL	C5V × 2
	Intermediate risk	C5V-DOXO × 4–6	C5V-DOXO × 2
	High risk	VCR-IRINO × 2 + C5V-DOXO × 6	
SIOPEL	Standard risk	CDDP × 4	CDDP × 2
	High risk	CDDP × 4 alternating with carbo/Doxo × 3	CDDP × 1 alternating with carbo/Doxo × 2
GPOH	Standard risk	PLADO × 2–3 or IPA	PLADO × 1
	High risk	CDDP × 4 alternating with carbo/Doxo × 3 or carbo/etoposide	CDDP × 1 alternating with carbo/Doxo × 2
JPLT	PRETEXT I	–	CITA × 4 (50% DOSE)
	PRETEXT II	CITA × 2	CITA × 4 (50% DOSE)
	PRETEXT III/ IV or EVPH+ M+	CITA × 4 CITA × 4+ high dose etoposide/carbo/Melphalan ± HACE	CITA × 2 CITA × 2

C5V cisplatin +5-fluorouracil + vincristine, *CDDP* cisplatin, *carbo* carboplatin, *Doxo* doxorubicin, *PLADO* cisplatin + doxorubicin; *CITA* cisplatin + pirarubicin, *EVPHM* extrahepatic/venous involvement/portal vein invasion/tumor rupture/metastasis, *IPA* ifosfamide/cisplatin/doxorubicin, *HACE* hepatic artery chemoembolization, *COG* Children's oncology group, *SIOPEL* International Society of Pediatric Oncology-Liver Tumour Strategy Group, *GPOH* German Pediatric Hematology Group, *JPLT* Japanese Pediatric Liver Tumor Study Group, *VCR* vincristine; Irino, irinotecan

7 Surgical Management

Surgery is a key component in management of hepatoblastoma, and complete resection is essential to improve outcome. However, over 50% of HB are unresectable at diagnosis [34]. SIOPEL recommends complete surgical resection of primary tumor as well as metastatic sites, the timing of surgery being generally after four or seven cycles of neoadjuvant chemotherapy. Delaying surgery further has not been found beneficial [41]. The current COG protocol AHEP0731 recommends upfront surgical resection (lobectomy or segmentectomy) in PRETEXT I tumors and selected PRETEXT II tumors which are completely resectable. POSTTEXT II and III without macroscopic venous involvement are recommended to undergo neoadjuvant chemotherapy followed by lobectomy or trisegmentectomy. POSTTEXT III tumors with macroscopic venous involvement or POSTTEXT IV tumors would require neoadjuvant chemotherapy followed by re-evaluation for surgery—these tumors might require extreme/complex resection or even orthotropic liver transplantation. Incomplete resection and macroscopic residual disease confer a worse outcome, and if these are anticipated, orthotropic liver transplantation (OLT) should be performed [36]. Successive trials optimizing chemotherapy have increased the resectability of tumors (see Table 3). Atypical, nonanatomic or wedge resections are associated with inferior outcomes and thus not recommended.

7.1 Surgery for Lung Metastases

Lung metastases often respond well to neoadjuvant chemotherapy and may completely disappear. Residual metastatic disease needs to be surgically removed. Wedge resection is a preferred technique for the removal of pulmonary deposits.

7.2 Role of Orthotropic Liver Transplantation [42]

The advent and increasing use of OLT have enabled increased resection in hepatoblastoma. Although OLT necessitates infrastructure, resources and long-term immunosuppression in small children, it is preferred over risky surgery in certain subsets of patients. Indications for OLT include:

- Multifocal HB in all four liver sections (PRETEXT IV)
- Solitary PRETEXT IV HB that are not clearly downstaged to POSTTEXT III
- Portal vein involvement
- Involvement of all three hepatic veins (V3)
- Central HB (if a conventional resection does not seem feasible

The current COG study (AHEP0731) advocates early referral for OLT, i.e., based on imaging done **after** the second cycle of chemotherapy. Posttransplantation chemotherapy has been observed to improve survival and hence should be administered even at the cost of increased toxicity.

The Pediatric Liver Unresectable Tumor Observatory (PLUTO) is an online registry which collects information on unresectable HB, mostly those undergoing OLT.

8 Medical Management

Hepatoblastoma is a chemosensitive tumor. The current chemotherapeutic strategies in hepatoblastoma are a result of multiple collaborative studies, mainly by SIOPEL and COG (see Table 3). Optimization of chemotherapy has been a key reason for improved outcomes in HB, especially since over half tumors are unresectable at diagnosis. The earlier trials recognized cisplatin to be the most effective chemotherapeutic agent in HB, and it is the backbone of all chemotherapeutic regimens.

Neoadjuvant chemotherapy has been found to reduce tumor size and volume, decrease vascularity and demarcate it from normal liver tissue, thus increasing resectability. It may also lead to the complete disappearance of macroscopic lung metastases and act on microscopic metastasis. These are the rationale behind the SIOPEL approach of neoadjuvant chemotherapy followed by delayed surgery. SIOPEL chemotherapy in standard-risk hepatoblastoma consists of four cycles of cisplatin monotherapy followed by surgery and two more cycles of cisplatin. SIOPEL chemotherapy in high-risk hepatoblastoma consists of ten cycles of alternating cisplatin and carboplatin/doxorubicin (SUPER PLADO); this strategy allows for a higher dose of platinum while decreasing the dose of toxic cisplatin (see Table 5). The North American (currently COG) groups prefer surgery wherever safely possible followed by adjuvant chemotherapy. Stage 1 tumors with pure fetal histology can be safely observed after complete resection [20]. The current COG trial, AHEP 0731 is testing the efficacy of further reduction in therapy [36]. There are four risk groups (see Table 5): “very low risk” patients are observed after surgery, and “low-risk” patients undergo surgery followed by two courses of adjuvant chemotherapy with cisplatin, fluorouracil IV and vincristine (regimen T). “Intermediate-risk” patients on AHEP0731 receive six courses of C5VD chemotherapy with cisplatin, fluorouracil, vincristine and doxorubicin (regimen F) with surgery (± liver transplantation) after two to four courses. “High-risk” patients receive two courses of upfront VIT chemotherapy with vincristine, irinotecan and temsirolimus followed by six courses of C5VD interspersed with VIT (regimen H) and surgery after course 4. No controlled comparison has been performed between the SIOPEL and

COG treatment strategies. However, the survival rates of patients treated with both approaches are comparable.

9 Other Modalities of Treatment

Tumors which are unresectable even after neoadjuvant chemotherapy may benefit from alternative approaches, the most promising of which is transarterial or hepatic artery chemoembolization (TACE/HACE), which has been used to improve resectability of HBs [43]. Intra-arterial chemotherapy with drugs such as cisplatin and doxorubicin is followed by embolization of the feeding arteries of the tumor.

Currently, there is no evidence for use of radiotherapy in hepatoblastoma unless in palliative setting.

10 Toxicity of Treatment in Hepatoblastoma

Hepatoblastoma is typically a disease of very young children, who are at risk for acute toxicities as well as late effects of treatment. The major toxicities include ototoxicity, renal tubular toxicity and cardiotoxicity. Understanding of these toxicities has led to increasing use of risk-stratified treatment to avoid unnecessary treatment exposures in a large proportion of children.

10.1 Ototoxicity

Hearing loss is often a permanent side effect of cisplatin chemotherapy; SIOPEL studies have shown that over 60% of children had permanent high-frequency hearing loss [44]. Since affected children are often very young, hearing loss can affect development of speech, learning and overall development. Age-appropriate monitoring of hearing needs to be done during, and after completion of treatment, with pure-tone audiometry being the standard in older children. Two large studies from COG and SIOPEL have found that sodium thiosulfate is safe and efficacious in reducing the incidence of cisplatin induced hearing loss, when given 6 h after cisplatin infusion. While the COG study ACCL0431 included multiple tumor diagnoses, SIOPEL-6 was restricted to children with standard-risk hepatoblastoma [32, 45].

10.2 Nephrotoxicity

Both glomerular and tubular toxicity are common with cisplatin. Judicious hydration and monitoring of renal function and electrolytes should be done during treatment and at follow-up.

10.3 Cardiotoxicity

High cumulative doses of doxorubicin place young children at high risk of acute and long-term cardiac toxicity. Periodic monitoring during and after treatment is essential. Current and upcoming trials such as AHEP 0731 and the PHITT trial recommend the use of cardioprotectant dexrazoxane.

11 Stage-Wise Prognosis with Current Treatment

Survival in standard-risk hepatoblastoma is uniformly good with 5-year event-free survival of 83% and overall survival of 95%, whereas 3-year event-free survival is 65% and 3-year overall survival is 69% in high-risk hepatoblastoma [29, 30]. Outcomes of hepatoblastoma in resource-limited settings are lower, mainly due to advanced presentations, treatment-related mortality, lack of appropriate risk stratification and paucity of centers with surgical expertise (including liver transplantation).

12 Management of Recurrent Disease Including Specific Palliative Measures

Recurrent hepatoblastoma is a challenge to treat. Prognosis depends on previous treatment, site of recurrence and extent of disease spread.

Second-line chemotherapy regimens would depend on initial treatment. Combination of vincristine-irinotecan and addition of doxorubicin have been tried with limited success. Aggressive and complete resection improves the outcome, and liver transplantation should be considered in difficult resections [46].

Summary

- Hepatoblastoma (HB) is the most common primary malignant liver neoplasm in children,
- Comprises only 1% of all pediatric malignancies.
- Diagnostic investigations include serum alpha-fetoprotein (AFP), which is elevated for age, and imaging, preferably triple-phase contrast-enhanced CT abdomen/MRI.
- The PRETEXT system is used to define the extent of liver involvement and determine operability, and has prognostic implications.
- Conventionally, hepatoblastoma is risk stratified into standard (good) risk and high risk, and current treatment is based on decades of collaborative efforts.
- Hepatoblastoma requires multidisciplinary management of which surgery is the mainstay.
- Young children need careful monitoring for the development of acute and late toxicities of treatment.

Abbreviations

ALL	Acute lymphoblastic leukemia
AML	Acute myeloid leukemia
ARI	Acute renal injury
CTLS	Clinical TLS
LTLS	Laboratory TLS
NHL	Non-Hodgkin lymphoma
SVC	Superior vena cava
SVCO	SVC obstruction syndrome
TLS	Tumor lysis syndrome

1 Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is an oncologic emergency resulting from rapid cell death. It can happen either spontaneously or after initiation of chemotherapy. Cairo and Bishop [1] defined TLS as either laboratory TLS (LTLS) or clinical TLS (CTLS). LTLS is defined as the occurrence of two or more of the following abnormalities, 3 days before or 7 days after initiation of chemotherapy: 1) 25% decrease from baseline in serum calcium and/or 2) 25% increase from baseline in the serum values of uric acid, potassium, or phosphorous. CTLS defined as presence of LTLS along with one or more clinical manifestations like cardiac arrhythmia, death, seizure, or acute renal injury (ARI) with an elevated serum creatinine >1.5 times upper limit of normal. Wilson and Berns [2] have modified definition of ARI, 0.3 mg/dL absolute increase, or relative 50% increase in creatinine over baseline.

1.1 Incidence and Risk Factors

TLS is more common in patients with tumors that have a large tumor mass and a high proliferation rate. Hematologic malignancies such as non-Hodgkin lymphoma (NHL), particularly Burkitt-type lymphoma, acute lymphocytic and lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML), chronic leukemias, and multiple myeloma are associated with increased of TLS. Rarely, TLS can develop in solid malignancies like small-cell carcinoma of the lung, germ cell tumors, neuroblastoma, and breast carcinoma.

1.2 Pathophysiology

Rapid lysis of tumor cells either spontaneously or as a consequence of chemotherapy and releases intracellular contents like potassium, phosphorus, and nucleic acids. This causes a diversity of biochemical changes which leads to different clinical signs of TLS. Hyperkalemia can cause arrhythmias and sudden death. Hyperphosphatemia can cause formation of calcium phosphate complexes which crystallizes renal tubules, leading to ARI. The resulting hypocalcemia causes symptoms like tetany, seizures, and dysrhythmia.

Nucleic acids are metabolized to hypoxanthine, xanthine, and finally to uric acid by xanthine oxidase enzyme. Hyperuricemia can cause urate crystallization and precipitation in renal tubules leading to ARI. Increased serum uric acid levels can induce ARI by further mechanisms, like renal vasoconstriction, reduction in endothelial cell nitric oxide, and activation of the renin–angiotensin system [3]. Renal clearance of uric acid depends on glomerular filtration rate and urine pH (enhanced by urine alkalinization). Therefore,

crystal-induced ARI can be caused by uric acid, calcium phosphate, and xanthine precipitation.

Patients are classified into three risk groups (high, intermediate, and low risk) as per patient-related factors (preexistent renal dysfunction and hyperuricemia) and tumor-related factors (tumor mass, type of tumor [indicated by stage of tumor, white blood cell counts, and LDH levels]) [4].

1.3 Prevention and Treatment

Since TLS is a life-threatening emergency, prevention of TLS is the key principle in its management. It is recommended to start with a low-dose therapy in highly chemosensitive tumors with high tumor burden. In patients, at intermediate and high risk for TLS, it is necessary to monitor serum electrolytes and renal function tests at least twice daily, before starting systemic therapy and during the first 7 days of treatment.

1.3.1 Hydration

Hydration should be done with normal saline at a rate of 3 L/m^2/24 h, especially in patients with intermediate and high risk for TLS. Close monitoring of fluid intake and output is required, and a urinary output 100 mL/h 24 h should be targeted. Hydration must begin before starting systemic therapy and through the duration of treatment (at least for first 7 days). Special care should be done for elderly patients and those with cardiac dysfunction. In case of low urine output even after an optimal hydration, loop diuretics can be given. Thiazide diuretics should be avoided as they interact with allopurinol and can increase uric acid levels.

1.3.2 Electrolyte Abnormalities

Asymptomatic hypocalcemia should not be treated as it can lead to calcium phosphate crystal precipitation in renal tubules. Symptomatic hypocalcemia should be treated with infusion of calcium gluconate [5]. Potassium should not be added to hydration fluid to avoid hyperkalemia. Patients with potassium levels >6 mmol/L should be carefully observed, and immediate treatment should be given (infusion of calcium gluconate, insulin and glucose infusion, and therapy with β-adrenergic agonists).

Oral phosphate binders like Sevelamer or antacids syrup can be used to treat hyperphosphatemia. These measures are usually less effective. Significant hyperphosphatemia is best treated with hemodialysis (renal replacement therapy).

1.3.3 Renal Replacement Therapy

Renal replacement therapy should be considered for patients with severe acidosis, persistent hyperkalemia inspite of adequate therapy, and volume overload despite diuretic therapy.

1.3.4 Alkalinization of Urine

Alkalinization of urine was historically recommended in the management of TLS as it may increase the solubility of uric acid in urine. However, recent evidence advocates that urine alkalinization increases the risk of calcium phosphate precipitation in the renal tubules, especially in patients with hyperphosphatemia. Hence, alkalinization of urine is not being recommended now in TLS prophylaxis [6].

1.3.5 Antihyperuricemic Therapy

Hyperuricemia plays a key role in evolving ARI [3]. The most commonly used antihyperuricemic agents are allopurinol (xanthine oxidase inhibitor) and rasburicase (recombinant urate oxidase).

Allopurinol

Allopurinol prevents the conversion of hypoxanthine to xanthine and xanthine to uric acid. Hypoxanthine and xanthine are cleared ten times faster than uric acid by renal tubules. Allopurinol requires dose adjustment in case of renal dysfunction. It should be started one day prior to initiation of anticancer therapy and be continued until normalization of uric acid levels. However, allopurinol cannot decrease the level of preexisting uric acid and can lead to increases in serum levels of xanthine and hypoxanthine, which can cause xanthine nephropathy [7]. Therefore, allopurinol can be used for patients at low or intermediate risk for TLS. In case of established TLS, rasburicase should be considered.

Febuxostat

Febuxostat is a selective xanthine oxidase inhibitor [8] and has biliary elimination [9]. In patients with renal dysfunction or with hypersensitivity to allopurinol, febuxostat is an alternative option.

Rasburicase

Rasburicase is a recombinant, urate oxidase enzyme that convert uric acid is to allantoin. Allantoin is ten times more soluble than uric acid and thus easily cleared through renal tubules [10].

The FDA-approved dose is 0.15–0.20 mg/kg/day as a single intravenous infusion for 5 days. Several trials compared a single dose of rasburicase with daily dosing for 5 days. The single dose of rasburicase was as efficient as the multiple day dosing regimen for majority of patients [11–15].

A meta-analysis [16] compared the efficacy of a single-fixed dose of rasburicase versus the dose for 5 days versus allopurinol in adult patients at high risk for TLS (10 studies). This analysis proved that a single-fixed dose of rasburicase is noninferior to 5 days regimen and rasburicase was superior to allopurinol. Rasburicase is contraindicated in patient with

G6PD deficiency as it can lead to methemoglobinemia in G6PD-deficient patients [17].

2 Conclusion

TLS is a life-threatening emergency that can occur either spontaneously or after anticancer therapy. Prevention is the most effective therapy. Recognition of patients at risk for TLS is crucial. The diagnostic criteria and classification proposed by Cairo and Bishop facilitate early risk stratification of patients. Hydration with close monitoring of intake and output balance and serum electrolytes levels is crucial.

2.1 Pediatric Emergencies

Children with cancer are at increased risk of life-threatening emergencies, either from the cancer or due to treatment of cancer [18]. These conditions need to be diagnosed and treated early to lessen morbidity and mortality. Pediatric emergencies are broadly divided into cardiothoracic and abdominal emergencies.

2.2 Cardiothoracic Emergencies

2.2.1 Superior Vena Cava Syndrome

Obstruction of the superior vena cava (SVC) causes venous congestion leading to a constellation of signs and symptoms called as SVC obstruction syndrome (SVCO) [19]. SVC obstruction can be caused either by extrinsic or intrinsic obstruction. An anterior mediastinal mass (by either lymphoma or leukemia]) is the most common cause of SVCO [2]. Other common malignancies that can cause SVCO are lung cancer, neuroblastoma, and germ-cell tumors [19]. Prolonged placement of central venous catheter is also a risk factor of acquiring SVC thrombosis [20]. The common symptoms are facial swelling, cough, dyspnea, orthopnea, and wheeze. Chest X ray shows mediastinal widening and airway compression due to mediastinal mass [20, 21]. Contrast-enhanced CT scan of chest shows tumor and its extension into surrounding vasculature and airway. Diagnosis of mediastinal mass leading to SVC syndrome should be made with the least invasive technique to avoid cardiorespiratory compromise [21, 22]. Peripheral blood analysis for surface markers studies, pleural fluid cytology and cell block preparation, bone marrow aspiration, or biopsy of the most easily accessible extra-thoracic lesions (cervical/axillary lymph nodes) should be done before attempting biopsy from mediastinal mass. Treatment includes steroids, radiation therapy for radiosensitive tumors, and early initiation of chemotherapy [22].

2.2.2 Cardiac Tamponade

Common causes are tumor involving pericardium, opportunistic infection in immunocompromised patients, or fibrosis secondary to previous radiation [23]. Common tumors that invade the pericardium are leukemia and lymphoma [23, 24]. Cause of neonatal pericardial effusion is cardiac hemangioma [25]. The classical presentation of cardiac tamponade is hypotension, increased jugular venous pressure, and subdued heart sounds. Children may present with tachycardia, chest pain, cough, dyspnea, and pulsus paradoxus. Chest X-ray shows a globular-shaped enlarged cardiac shadow, known as “water bottle” shape [26]. Echocardiography shows fluid around the heart and may also show thickening of the pericardium due to pericarditis or pericardial tumor. CT scan shows compression of the cardiac chambers by effusion, nodular lesions, thickening of the pericardium, or hemorrhage [27]. Supportive care for cardiac tamponade includes oxygen and patient positioning to maximize cardiac output. Percutaneous catheter drainage should be done immediately to relieve the symptoms [28].

2.3 Abdominal Oncologic Emergencies

2.3.1 Intestinal Obstruction and Intussusception

Common tumors that presents with intestinal obstruction are abdominal Burkett’s lymphoma, large renal/adrenal tumor, ovarian and colon tumors, sarcoma, and presacral teratoma [18]. Vinca alkaloids and narcotics can cause paralytic ileus. Children present with abdominal pain and bilious vomiting. Diagnostic radiologic studies should begin with supine, erect, and left lateral decubitus abdominal films, which shows multiple dilated loops of bowel with air–fluid levels [29]. With paralytic ileus, there is uniform dilatation of the entire small and large bowels. Malignant tumors (Burkitt lymphoma and carcinoid tumor) can present with intussusception [29]. Small-bowel obstruction is managed initially by keeping the patient nil orally and placing a nasogastric tube for decompression. Evaluation for the underlying etiology should proceed simultaneously and chemotherapy to be started early as the tumor in paediatric age group are chemosensitive.

2.3.2 Acute Pancreatitis

Acute pancreatitis in children is usually caused by drugs, like L-asparaginase, corticosteroids, 6-mercaptopurine, used in the treatment of ALL [30]. Patients typically present with severe abdominal pain, nausea, vomiting, and soon after starting L-asparaginase therapy. The diagnosis of acute pancreatitis is based on clinical and laboratory values of raised amylase and lipase levels. Ultrasound abdomen can be normal in mild acute pancreatitis; however, in severe cases, the pancreas is enlarged and hypoechoic [29]. CT shows focal or diffuse pancreatic enlargement and often to peripancreatic fluid collection. Early fluid resuscitation is critically important as patients lose a large amount of fluids due to third spacing. Strict input and output monitoring is essential to decide on the rate of fluid infusion. Nasojejunal feedings with a low-fat formulation should be initiated as and when patient's pain and anorexia resolves. Total parental nutrition may be required if caloric needs per day are not met with enteral feeding or if patient is not tolerating the oral feeds [31]. Patients should be started on broad-spectrum antibiotics as patients are usually immunocompromised and early in treatment phase of their cancer. Patients should be monitored for development of complications like pseudo cyst formation, necrosis, abscess, and hemorrhage [32].

2.4 Neutropenic Colitis

Neutropenic colitis is a necrotizing colitis that mostly involves the cecum, ascending colon, appendix, and terminal ileum, in neutropenic patients predominantly with hematologic malignancies [18].

The majority of children presents with abdominal pain, fever, abdominal tenderness, and diarrhea [33]. Child presents with these complaints typically at nadir neutrophil counts. USG abdomen and pelvis shows bowel wall thickening (>3 mm), pneumatosis intestinalis, and free fluid [33]. Conservative management includes—fluid management, pain control, broad-spectrum antibiotics to cover gram-negative pathogens, and clindamycin or metronidazole for gastrointestinal anaerobes and often antifungal agents [34]. Surgical intervention is required in following conditions: persistent gastrointestinal bleeding despite resolution of thrombocytopenia and correction of clotting abnormalities; presence of free air (as seen in CT abdomen); and uncontrolled sepsis from intestinal infarction [34].

3 Brain Metastases and Spinal Cord Compression

Brain metastases (BM) are common intracranial tumors and occur in 20% to 40% of all solid cancer patients [35]. The most frequent primaries contributing to brain metastasis are lung, breast, and melanoma (7%–16%).

3.1 Imaging

Magnetic resonance imaging (MRI) plain with contrast is the first line of investigation and is used for diagnosing and differentiating BM from other intracranial tumors. It is also helpful in assessing the response to treatment.

3.2 Treatment

There are multiple treatment options including surgical resection, radiation therapy, and/or chemotherapy. Choice of therapy is based on patient's prognosis or survival. Localized therapies (surgery, stereotactic radiosurgery) are considered for patients with better prognosis. The prognosis can be gauged from several prognostic scoring systems that have been developed. These include the Recursive Partitioning Analysis (RPA), Basic Score for BM (BSBM), Score Index for Radiosurgery (SIR), Golden Grading System (GGS), and Graded Prognostic Assessment (GPA) classification systems [36].

3.3 Surgery

Surgery plays a significant role in the management of BM. It helps in achieving decompression, thus provides instant relief of symptoms secondary to mass effect. In addition, it provides tissue for histopathological evaluation and for molecular analysis. The surgery for BM is indicated for patients who has ECOG PS 0–2, good prognosis, lesion below 3 cm, and lesion in accessible locations. However, surgery can be performed for large lesions, with significant mass effect, or symptomatic lesions, even for palliative purposes if clinically warranted.

The early randomized trials by Patchell et al. demonstrated complete resection at surgery as the best management strategy for single BM [37]. The patients with a single BM were randomized to surgery plus whole brain radiation therapy (WBRT) or biopsy plus WBRT. The results showed survival benefit to surgical resection (OS 40 weeks vs. 15 weeks, $p < 0.01$) and better local control. Subsequently, the same group studied single BM with complete surgical resection randomized to WBRT or observation. The post-surgery WBRT decreased intracranial failure from 70% to 18% ($p < 0.001$) and also reduced local recurrence from 46% to 10% ($p < 0.001$).

3.4 Adjuvant Radiotherapy

Since Patchell et al. [38] initial results, multiple series using improved stereotactic guidance, modern surgical techniques, and MR imaging have shown that the rate of recurrence post-surgery alone was reduced to 50%. To reduce postoperative recurrence, radiosurgery or radiotherapy is recommended. However, WBRT comes with substantial cost of neurocognitive decline and hence efforts to avoid it are considered.

In a randomized trial comparing WBRT to SRS, equivalent OS for postoperative SRS and WBRT (median OS: 12.2 vs.11.6 months, respectively; $p = 0.70$) were demonstrated. 85% patients post WBRT had cognitive deterioration at 6 months posttreatment as compared to only 52% with SRS

($p < 0.001$). Postoperative SRS is standard of care after surgically resected metastases. However, WBRT is associated with better surgical bed control rates at 12 months (81 vs 61%; $p < 0.001$).

3.5 One to Four BM

In a randomized study of two to four BM, all <2.5 cm with WBRT vs. WBRT plus SRS boost showed better control with SRS boost (100% vs. 8%) and survival (11 vs. 7.5 m) [39]. RTOG 95-08 randomized 300 patients similarly and showed improved local control at 1 year 71%–82% but no survival difference [40]. In patients with single BM or recursive partition analysis (RPA) Class I, SRS boost has shown improved survival from 4.9 to 6.5 months ($p = 0.39$) and 9.6 to 11.6 months ($p = 0.045$), respectively. When patients were analyzed by GPA score, it was found that patients with a high GPA (3.5–4) had improved survival irrespective of number of BMs. This study showed that SRS boost improves local control and OS, principally in patients with good performance status [40].

A Cochrane Database updated review for all three randomized trials ($n = 358$) showed that with the use of WBRT plus SRS, there was decrease in local failure (HR 0.27 95% CI 0.14–0.52), improved performance status scores and decreased steroid use (RR 0.64 CI 0.42–0.97). There was no difference in survival between the groups, though participants with single BM had significantly longer median survival in the WBRT plus SRS group ($p = 0.04$) [41].

In a phase III study (Aoyama et al.; $n = 132$), it was seen that local failure rates reduced from 76 to 47% by adding WBRT to SRS, in patients with four or less BM with size <3 cm [42]. However, survival of patients did not improve by adding WBRT [42]. In EORTC phase III study, patients with one to three BM who underwent SRS or surgery were randomized to WBRT or observation did not show any difference in survival between the groups [43]. An individual patient-level meta-analysis of the multiple studies showed that patients younger than 50 years of age had an improved survival with SRS alone compared to SRS plus WBRT (10 vs. 8.2 months, $p = 0.04$).

Above trials and analyses have standardized the treatment of patients with one to four BM. We have learned that there is no negative impact on the OS by eliminating WBRT, there is improved local control with SRS plus WBRT and the risk of neurocognitive decline is lower with SRS alone.

3.6 Neurocognitive Sparing

The neuroprotective drugs are being increasing used to preserve cognitive function for patients requiring WBRT. Memantine is an antagonist of the *N*-methyl-D-aspartate (NMDA) receptor, which has important roles in learning and memory. The RTOG 0614 explored memantine for reducing neurocognitive decline. In this phase III trial, there was a trend toward delayed recall improvement but did not reach statistical significance ($p = 0.059$). In addition, there was delayed time to cognitive decline, reduced rate of decline in memory, executive function, and processing speed [44].

3.7 More than Four Metastases

The optimal radiation modality for patients with 5–15 BM (SRS or WBRT) is not clear. Though multiple retrospective and prospective papers have already shown feasibility of SRS alone in patients with up to 10 BM. However, a randomized study by the Canadian Cancer Trials Group (CCTG)-lead North American intergroup trial is ongoing testing this. Yamamoto et al. prospective observational study of SRS alone for treatment of 5–0 BM showed that overall survival was similar between patients with 2–4 metastases as compared to 5–10 metastases with no difference in acute toxicities but this data needs validation in future studies.

3.8 Systemic Therapy

In general, the chemotherapy is not considered an effective mode of controlling BM due to limited penetration of BBB.

3.9 Medical Management with Targeted Therapy

Longer survival in metastatic patients treated with targeted therapy increasing chances of developing BM. It is also postulated that this relegates the brain as a “sanctuary” site in which undetected intracranial micromets are sheltered from systemic treatment that is unable to penetrate the “sanctuary” of the BBB (Her 2 Breast Cancer, BRAF mutant melanoma). Recently, some newer targeted agents are demonstrated to cross BBB and may help in controlling BM. Some of the data is listed in Table 1 [45].

3.10 Immunotherapy

Brain has long been viewed as an immune-privileged environment. Emerging clinical data also suggest existence of stimulation of peripheral T cells leading to antitumor effects in the brain across BBB by using immune checkpoint inhibitors. The immunotherapeutic agents like pembrolizumab have shown response rates of 20%–30% in patients with melanoma or nonsmall cell lung cancer (NSCLC) BM. The

Table 1 Targeted agents in BM

Targeted therapy	Primary malignancy	Level of evidence	Best available outcome
ALK-directed therapy			
Crizotinib	Nonsmall cell lung cancer	Subgroup phase 3	12-week DCR 85% vs. 45% with chemo
Ceritinib		Subgroup P2	RR: 45%
Alectinib		Pooled Ph2	RR: 64%
Brigatinib		Subgroup Ph2	RR: 78% vs. 29% with crizotinib
EGFR-directed therapy			
Erlotinib	Nonsmall cell lung cancer	Phase 2 Phase 3	PFS: 10.1 months alone, 60% RR with RT RT = Erlotnib: Med OS: 6.1 m
Osimertinib		Phase 3	PFS at 6 months: 87% vs. 71% (std E-TKI) PFS at 18 months: 58% vs. 40%
HER2-directed therapy			
Lapatinib + Capecitabine	Breast cancer	Phase 2	BM IC-RR: 66%
Neratinib + Capecitabine		Phase 2	12-month OS: 63%
BRAF-MEK			
Vemurafenib		Phase 2	RR: 18%
Dabrafenib	Melanoma	Phase 2	RR of 40% in Rx naïve and 30% in prev Rx
Dabrafenib + Trametinib		Phase 2	RR: 44–59%
VEGF pathway Bevacizumab + Carboplatin	Breast cancer	Phase 2	RR: 45%

nivolumab and ipilimumab combination had shown a response rate of 55% in patients with melanoma BM [46]. Similarly, prolonged control rates are reported in lung, melanoma, RCC BM when patients on immunotherapy and received various types of radiotherapy for BM. At present, more data are needed to confirm these results, determine mechanisms of efficacy and resistance and for concrete recommendations.

3.11 Spinal Cord Compression

Epidural spinal cord compression is one of the commonest methods of neoplastic spinal cord compression. The importance of recognizing and acting fast is imperative as neurological signs like paraplegia or paraparesis can be reversed if treatment is started within 48 h of their occurrence. MRI spine is an important investigation guiding treatment. The selection of treatment needs to take into account three factors.

1. Mechanical stability of the spine
2. Radiosensitivity of the neoplasm
3. Overall prognosis of the disease

3.11.1 Mechanical Stability of the Spine

It should be assessed using Spine Instability Neoplastic score [47]. If we have a score of 7 or more than there is spinal instability and it warrants surgical consultation. Irrespective of the radiosensitive nature of the disease in presence of spine instability surgical intervention is required [48]. The score has a sensitivity and specificity of 96 and 80%, respectively, for predicting unstable lesions.

3.12 Radiosensitivity of the Neoplasm

The choice between surgical or radiation modality rests on this aspect. Radioresistant tumors should be addressed by surgical methods.

3.12.1 Overall Prognosis of the Disease

The key question is whether we should aggressively treat the patient or not. A consultation with treating medical oncologists and briefing on the expected prognosis should help in this decision making. It is better than keeping a survival cut off the focus should be on whether a patient will be able to recover postoperative or post radiation or not. In addition to these points general antiedema measures should be provided like glucocorticoids, pain management, venous thromboembolism prophylaxis, and palliative care consultation.

4 Febrile Neutropenia

4.1 Definition

Febrile neutropenia is defined as single oral temperature measurement of >101 °F or a temperature of 100.4 °F sustained over 1 h, with an absolute neutrophil count (ANC) of <500 cells/mL, or an ANC that is expected to decrease to <500 cells/mL in the next 48 h [49].

4.2 Epidemiology

Febrile neutropenia is the most common life-threatening complication of cancer therapy. The frequency of febrile neutropenia is higher in patients with hematological malignancy than those with solid tumors [50]. In high-risk febrile neutropenic patients, major complications (e.g., hypotension; acute renal, respiratory, or heart failure) occur in approximately 25%–30% of patients and mortality is approximately 11% [50].

Risk of FN is higher in case of low first-cycle nadir neutrophil count, prior history of neutropenic fever, prolonged duration of neutropenia, the magnitude of neutropenia, chemotherapy intensity, older age, female sex, low performance status, low albumin level, associated anemia, bone marrow involvement, and preexisting organ dysfunction [51].

4.3 Pathophysiology

The causative organisms could be gram positive, gram negative, or anaerobes. The most common gram-negative organisms in this setting are *Escherichia coli*, *Klebsiella* species, and *Pseudomonas aeruginosa*. The most common gram-positive organisms are coagulase-negative staphylococci, *Staphylococcus aureus*, viridans group streptococci, and *Enterococcus* species. Anaerobes are found in <5% of cases, and fungi (predominantly *Candida* and *Aspergillus* species) are found in 2%–10% of at-risk patients (i.e., those with severe, protracted neutropenia [neutrophil count <100 cells/mL for more than 7 days]), a history of corticosteroid use; older age; status post-intensive chemotherapy; central catheters; advanced-stage disease; or evidence of tissue damage) [52].

4.4 Differential Diagnosis

Common causes of fever in cancer patients that need to be differentiated from FN are drug-induced fever, tumor-associated fever, thromboembolism, and paraneoplastic syndromes.

Neutropenic patients are a heterogeneous population, with subgroups with varying risks regarding response to initial therapy, development of serious medical complications, and mortality. Various scoring systems are available that can differentiate patients into low- or high-risk group and guide management of patient with febrile neutropenia. The most commonly used scoring system in clinical practice is MASCC score [53], which accurately identifies patients, at the time of presentation into low risk and high risk of complications.

The following investigations should be done in patients with FN:

1. Complete blood counts with differentials
2. Kidney function tests and liver functions tests
3. *Blood cultures and fungal cultures:* Peripheral blood culture should be collected before starting intravenous antibiotics. If patient has central venous catheter, then concomitant blood cultures should be drawn peripherally and from central venous catheters. Differential time to positivity of >120 min between the central venous catheter and peripheral cultures is diagnostic of catheter-related infection. Fungal cultures should be sent in patients with a prior history of fungal infections, patients who are on steroids, patients with indwelling catheters or in case of radiological examination suggestive of fungal infections. Central venous catheters should be removed in the setting of catheter-related infections or fungemia [54].
4. *Chest X-rays /echocardiography:* Chest X-ray should be done in all patients with FN especially those who requires hospital admission as these patients may not have signs and symptoms of respiratory infections. Echocardiogram should be considered in patients with clinical signs and symptoms of cardiac failure, in case of persistent fever when no other focus is found, persistent bacteremia due to an organism such as enterococci or viridans group streptococci, and those with persistent fungemia.
5. *Stool/urine cultures:* Urine routine examination may not show pus cells in neutropenic patients, urine culture must be done irrespective of urine routine report if urinary tract infection is clinically suspected. If patients present with loose stools or signs suggestive of colitis, then stool culture must be sent.

Common organisms causing colitis are *Clostridium difficile* and other pathogens such as *Salmonella*, *Shigella*, *Campylobacter*, norovirus, cytomegalovirus, or rotavirus.

4.5 CECT (Thorax and Abdomen and Pelvis)

Chest CT scans are more sensitive than a chest X-ray and demonstrate the presence of pulmonary infiltrates far more frequently in this setting [55].

4.6 Management

4.6.1 Primary Options

The first dose of antibiotics should be administered within 1 h of a neutropenic patient presenting with fever [49, 56].

At-risk patients include those with severe, protracted neutropenia; with a history of corticosteroid use; older age (>65 years); status post-intensive chemotherapy; with central catheters; with more advanced stage of disease; and with evidence of tissue damage [52].

Empiric monotherapy with piperacillin/tazobactam, cefaperazone/sulbactam, cefepime is an acceptable option. Combination therapy with an aminoglycoside can be considered, with early discontinuation of the aminoglycoside if cultures do not reveal evidence of a drug-resistant pathogen infection. The choice of antibiotics depends on local institutional bacterial susceptibilities [57]. Combination therapy with cefaperazone/sulbactam and an aminoglycoside may be preferable in high-risk patients with prolonged neutropenia [56]. Once antibiotics are started, the median time to clinical response is 5–7 days, and antibiotics do not need to be changed despite persistence of fever for the first 3–5 days [58].

Antibiotics that cover gram-positive organisms should be started if there is evidence of grade III/IV mucositis, past history of blood infection with gram-positive organism, patients who presents with hypotension, cellulitis or if there is radiological evidence of staphylococcus pneumonia. The Infectious Disease Society of America (IDSA) guidelines note that the presence of a central venous catheter is not an indication for empirical vancomycin [49].

In patients with documented infections, the duration of therapy depends on the specific organism and site of infection. Antibiotics may be continued for the duration of neutropenia (i.e., until absolute neutrophil count is ≥500 cells/mL), or longer if clinically necessary (10–14 days of treatment is usually sufficient for most infections) [49].

In patients with negative blood cultures and with an absolute neutrophil count ≤500 cells/mL, antibiotic therapy can be discontinued provided that they have been afebrile for 5–7 days and have no complications (the exception to this recommendation is high-risk patients with leukaemia, where antibiotic therapy is often continued for up to 10 days or until the absolute neutrophil count is ≥500 cells/mL) [56].

The use of empirical granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) in patients with febrile neutropenia is typically not recommended except in: high-risk patients with pneumonia, hypotension, multiorgan dysfunction (sepsis syndrome), invasive fungal infection, uncontrolled primary disease, or in patients who are persistently febrile (>10 days), have profound neutropenia (<100 cells/mL), are age >65 years, or were hospitalized at the time of fever development [59].

For low-risk patients who are candidates for outpatient management (i.e., those with solid tumors, expected neutropenia <7 days, stable vital signs, adherence to treatment, no organ dysfunction, tolerance of oral medications and fluids, residence ≤1 h from a clinic or hospital, and telephone and transport access), oral therapy with a fluoroquinolone (e.g., ciprofloxacin, levofloxacin, and moxifloxacin) plus amoxicillin/clavulanate (or clindamycin if the patient is penicillin allergic) is recommended [60, 61].

The choice of antifungal is often dictated by the resistance profile of the institution, risk factors for aspergillosis (patients on long term steroids, prolonged neutropenia), and the severity of illness: for example, more aggressive treatment with voriconazole or amphotericin-B if the patient is critically ill [49].

4.6.2 Prophylactic Use of GCSF

Guidelines from the National Comprehensive Cancer Network (NCCN), the American Society of Clinical Oncology (ASCO), and the European Organisation for Research and Treatment of Cancer (EORTC) recommend the use of granulocyte-macrophage colony-stimulating factor (GM-CSF) in patients at >20% risk for developing febrile neutropenia based on age, comorbid illness, disease characteristics, and myelotoxicity of the chemotherapy regimen [62, 63]. Meta-analyses have shown that granulocyte colony-stimulating factor (G-CSF) prophylaxis reduces the incidence of febrile neutropenia in adults undergoing chemotherapy for solid tumors and lymphoma [64].

4.6.3 Antibacterial and Antifungal Prophylaxis

Joint ASCO and Infectious Diseases Society of America (IDSA) guidelines recommend antibiotic prophylaxis with a fluoroquinolone for patients at high risk for febrile neutropenia or profound, protracted neutropenia, such as patients with acute myeloid leukemia, myelodysplastic syndromes, or hematopoietic stem-cell transplantation treated with myeloablative conditioning regimens [65].

4.6.4 Secondary Prevention

Patients with a history of febrile neutropenia are at risk for subsequent episodes of febrile neutropenia, and many professional societies including the American Society of Clinical Oncology (ASCO), the National Cancer Center Network (NCCN), and the European Organisation for Research and Treatment of Cancer (EORTC) recommend the routine use of colony-stimulating factors as secondary prophylaxis against febrile neutropenia with subsequent cycles of chemotherapy [59].

4.7 Complications

1. **Mortality:** Mortality from febrile neutropenia has decreased to less than 10% among patients who receive antibiotics promptly [66]. In contrast, mortality in low-

risk, febrile neutropenic patients is 1%–2% [67]. Mortality risk is higher in patients who present with hypotension and documented bacteremia (as high as 24%–82%) [68]. It is also increased in patients with pneumonia, uncontrolled cancer, polymicrobial infections, and older age [69].
2. **Clostridium difficile**
3. **Antibiotic-induced fungal overgrowth**
4. **Emergence of multidrug resistant infections**

4.8 Prognosis

Although mortality from febrile neutropenia has steadily declined, the condition is still associated with considerable morbidity and mortality. Approximately 20% to 30% of patients with febrile neutropenia present with complications that require in-hospital management [56].

5 Hypercalcemia of Malignancy

Hypercalcemia occurs in 20%–30% of patients with cancer [70, 71]. Common cancers that are associated with hypercalcemia are renal cancer, squamous cell carcinoma, breast cancer, ovarian cancer, endometrial cancer, and human T-lymphotropic virus-associated lymphoma [70, 72, 73].

5.1 Pathophysiology

Hypercalcemia is caused by three mechanisms:

1. Humoral—mediated by parathyroid hormone-related peptide (PTHrP) leads to activation of osteoclastic bone resorption and suppression of osteoblastic bone formation. This results in skeletal release of calcium and subsequent hypercalcaemia. PTHrP also acts at the level of the kidney to reduce calcium clearance, as well as to reduce the renal phosphorus threshold, leading to hyperphosphaturia and hypophosphataemia [70, 72].
2. Local osteolytic hypercalcemia: in the setting of malignancy with widespread skeletal involvement, local release of cytokines (e.g., IL-1 and IL-6), chemokines, and PTHrP leads to increased osteoclastic bone resorption and to increased release of calcium into the serum that overwhelms the kidney's capacity to clear calcium [72].
3. Hypercalcemia mediated by increased calcitriol (1,25 dihydroxy vitamin D) synthesis or ectopic parathyroid hormone secretion [73].

5.2 Diagnosis

Common presenting symptoms are gastrointestinal disturbance (anorexia, nausea, and constipation), polydipsia, polyuria, and bone pain. Some patients do present with fatigue, confusion, stupor, and coma [70, 72, 73]. Patients may have poor skin turgor or dry mucous membranes due to dehydration. However, hypercalcemia may not be associated with any specific physical examination findings. A thorough medication history to evaluate for use of medications that may cause or worsen hypercalcemia (thiazide diuretics, lithium, calcium, over-the-counter antacids, and large doses of vitamin D) should be undertaken [73].

5.2.1 Laboratory Evaluation

The following investigations should be sent when hypercalcemia is suspected—serum calcium, ionized calcium, renal function tests, serum albumin, serum phosphorous, serum parathyroid levels/parathyroid hormone-related peptide, resting ECG to assess for a shortened QT interval, and dysrhythmias.

5.2.2 Radiology Evaluation

A skeletal survey in patients in whom multiple myeloma, bone metastases, or leukemia are suspected. Chest X-ray to assess for lung cancer, sarcoidosis, or tuberculosis. Further imaging should be ordered, according to the suspected cancer or condition and the anatomical region involved [72].

5.3 Management

The treatment for hypercalcemia of malignancy depends on the underlying pathophysiology and severity of hypercalcemia. Hypercalcemia of malignancy resolves with definitive anticancer therapy.

5.3.1 Asymptomatic Patients with Mild Hypercalcemia

Serum Ca level of 10.5–12 mg/dL is defined as mild hypercalcemia. Such patients do not require immediate treatment, supportive measures include increase oral water intake, with hold calcium supplements IV or oral, and discontinuation of drugs causing hypercalcemia (vitamin D thiazide diuretics).

5.3.2 Symptomatic Patients with Serum Ca Levels Greater than 12 Mg/dL

Symptomatic patients with serum Ca levels greater than 12 mg/dL or patients with hypercalcemic crisis (serum calcium more than 14 mg/dL) should be admitted immediately and started on aggressive therapy that includes

1. Hydration: Most patients with hypercalcemia are dehydrated due decreased oral fluid intake resulting from nausea and vomiting and also secondary to renal dysfunction induced by hypercalcemia. Therefore, initial management is volume expansion with intravenous fluids, which increases the glomerular filtration rate and also excretion of calcium. Normal saline should be given at rate of 200 mL/h depending on renal function and dehydration status. Hydration should be continued until patient's serum calcium level is corrected within the normal range [73].
2. Diuretics: Once intravascular volume has been repleted, low-dose of furosemide (20–40 mg IV) every 12 h should be given which will further reduce the calcium level. It blocks calcium reabsorption in the loop of Henle and also increase urine output thus preventing fluid overload secondary to hyperhydration [73].
3. Bisphosphonates: Bisphosphonates are the most effective agents for treating malignancy-associated hypercalcaemia. Bisphosphonates effectively block osteoclastic bone resorption. Therapy should be instituted immediately upon diagnosis because response generally takes 2–4 days. Zoledronic acid is usually preferred and administered as a single dose [74]. Vitamin D should be measured (and corrected if deficient) prior to intravenous bisphosphonate therapy to avoid the risk of hypocalcemia. Regular monitoring of calcium levels is also important. If hypercalcemia is improved with the initial dose, but serum calcium levels begin to increase again, the dose may be repeated after 7 days. Denosumab is a monoclonal antibody directed against the receptor activator of nuclear factor-KappaB ligand (RANKL); it reduces osteoclast differentiation and bone resorption and is considered for patients who has hypercalcemia refractory to zoledronic acid.
4. Calcitonin: Calcitonin interferes with osteoclastic bone resorption [70]. It may cause a more rapid correction of hypercalcemia than bisphosphonates [75, 76]. The clinical utility of calcitonin is limited by its transient effect and availability [75, 76]. Potential adverse effects include flushing and nausea. Calcitonin may be used in the first 24–48 h following bisphosphonate administration to transiently reverse hypercalcaemia while awaiting the therapeutic effect of bisphosphonate therapy.
5. Dialysis can be considered in patients who have cancers that are likely to respond to therapy, but in whom renal and cardiac function limits utilization of intravenous hydration or accepted pharmacological therapy [77].

5.3.3 Vitamin D (1,25-Dihydroxyvitamin D)-Mediated Hypercalcaemia

Glucocorticoid therapy is efficacious in treating calcitriol (1,25-dihydroxyvitamin D)-mediated hypercalcaemia. No guidelines with respect to dosing and duration of therapy exist [70].

5.3.4 Ectopic Parathyroid Hormone Production

Removal of primary malignancy/ectopic parathyroid hormone-secreting source can reverse hypercalcemia [78].

5.4 Monitoring

The nadir in serum calcium levels following bisphosphonate administration typically occurs within 7 days. Responses last for 1–4 weeks [76]. Serial monitoring of calcium is, therefore, important. Eradication of underlying malignancy is crucial for continued maintenance of normal calcium level.

6 Thrombocytopenia

Thrombocytopenia is generally defined as platelet counts less than 150 * 10^9/L. It is further subdivided into mild (platelet count 100,000 to 150,000/microL), moderate (50,000 to 99,000/microL), and severe (<50,000/microL) [79–81]. Thrombocytopenia develops due to either increased destruction or decreased production of platelets. Increased loss of platelets happens in conditions like disseminated intravascular coagulation, thrombotic microangiopathies, or immune-mediated destruction of platelets [82, 83]. Decreased production happens in cases of bone marrow failure like leukemia, myelodysplastic syndromes, aplastic anemia, or chemotherapy induced.

6.1 History and Physical Examination

A thorough history and physical examination facilitate the diagnosis. Important aspects include the following:

- Family history of bleeding disorders and/or thrombocytopenia
- History of bleeding (e.g., petechiae, ecchymoses, epistaxis, gingival bleeding, hematemesis, melena, and heavy menstrual bleeding)
- Disease history like malignancies, infections, and autoimmune disorders [84]
- Medication exposures—e.g., aspirin, nonsteroidal anti-inflammatory drugs, and herbal remedies [81]
- Recent travel history for malaria, dengue fever, viral infections
- Recent transfusions/vaccinations [85]

6.2 Physical Examination

Physical examination should focus on site of bleeding, severity of bleeding, and other abnormalities on general examination like lymphadenopathy, hepatosplenomegaly, or skeletal abnormalities. Patients with thrombocytopenia presents with mucocutaneous bleeding, while the bleeding in joints or soft tissues suggests coagulation abnormalities, like DIC. The presence of skin necrosis should raise suspicion of heparin-induced thrombocytopenia (HIT).

6.3 Laboratory Testing

Peripheral blood smear: remains the most important investigation in diagnostic approach to thrombocytopenia. All three blood cell lineages should be assessed carefully, we can differentiate whether it is thrombotic microangiopathy (RBC fragmentation) or acute leukemia (blasts). Platelet clumping suggests the possibility of pseudo thrombocytopenia.

6.3.1 RBC and WBC Abnormalities

Abnormal RBC and WBC morphologies may suggest a specific condition. Examples include the following:

- Schistocytes suggest a microangiopathic process (e.g., DIC, TTP, HUS, and DITMA).
- Nucleated RBCs, and Howell–Jolly bodies, may be seen post-splenectomy or occasionally in patients with poor splenic function.
- Spherocytes suggest immune-mediated hemolytic anemia or hereditary spherocytosis.
- Leucoerythroblastic picture, teardrop cells, nucleated RBCs, or immature granulocytes suggest an infiltrative process in the bone marrow.
- Leukocytosis with a predominance of bands (left shift) and/or toxic granulations suggests infection
- Immature WBCs (e.g., myeloblasts) or dysplastic WBCs suggest leukemia or myelodysplasia.
- Multilobed/hypersegmented neutrophils (i.e., >5 lobes) suggest a megaloblastic process (e.g., B12/folate/copper deficiency).
- Combined anemia and thrombocytopenia can be seen if there has been longstanding bleeding (e.g., gastrointestinal) and also raise the possibility of systemic disorders.

A basic laboratory evaluation should include liver and renal function tests, a coagulation profile with D-dimers, serological testing (HIV and HCV), and measurement of lactate dehydrogenase.

Second stage of investigations should be impelled by clinical findings and the results of the peripheral blood smear. A bone marrow aspirate and biopsy should be done if cause of thrombocytopenia is unclear. If fraction of platelets in bone marrow aspirate are increased, it suggests hyper destructive thrombocytopenia (e.g., immune thrombocytopenia). If fraction of platelets in bone marrow aspirate are decreased or shows reticulated platelets, this suggest bone marrow failure [86, 87].

6.4 Management

Early recognition of the etiology of thrombocytopenia is crucial for the timely management of patients. The initial approach is based on the patient's history, physical examination, and the peripheral blood smear findings. The most common causes of thrombocytopenia are immune thrombocytopenia (ITP) and drug-induced thrombocytopenia (DTIP). Clinically, DITP can be confused with ITP and only a careful history taking can help in the correct diagnosis [88]. DITP should also be considered when patients have recurrent episodes of thrombocytopenia with rapid recovery.

6.4.1 Treatment of ITP

The decision to start therapy is based on bleeding tendency and on absolute platelet count. First line of therapy is steroids, and prednisolone at a dose of 1 to 2 mg/kg/day is given for 2 weeks. Once response is achieved, weekly dose reduction is done until a dose of 0.5 mg/kg is reached and then slow tapering by 5 mg/week [89]. In case of severe bleeding, immunoglobulins at a dose of 0.4–1 g/kg/day should be given as it leads to faster recovery of platelets [90]. Second-line therapy is indicated if there is only partial response to first-line therapy or patients develops thrombocytopenia again after an initial response. Rituximab 375 mg/m^2 per week for 4 weeks has shown long-term response rates of 40% [91]. The other drugs can be considered are cyclophosphamide, cyclosporin, and mycophenolate mofetil if there is no response to above therapies [92]. Newer therapies include thrombopoietin receptor agonist, romiplostim and eltrombopag, which have a response rates of 30%–40% and these medications are more effective in patients with chronic ITP [93]. Splenectomy is indicated patients who have no or only an insufficient response to all other treatment modalities, it has the highest rate of remissions from all ITP therapies, nearly 60% of patients will achieve complete response [94]. All patients must preoperatively receive Haemophilus influenzae b, pneumococcal, and meningococcal vaccinations before spleenectomy [95].

1 Introduction

The prevalence of cancer is rising globally, and in most countries, the disease is presenting for treatment late, as an incurable illness. Commonly patients with solid tumors present as asymptomatic masses. Around 15% of patients with nonmetastatic cancer have pain. Pain is considered as an independent predictor of disease progression. With better understanding of pain pathophysiology and underlying nociception, a great promise for optimum pain therapeutics is fast evolving. The rapid development of palliative concept world over has enhanced awareness of the long underreported and undertreated problem. Patients now have better access to pain specialists in western countries, but many patients in developing countries in need of pain management do not have even easy access to oral opioids. Inadequately treated pain continues to be a huge burden on the patients, healthcare system and society at large.

2 Pain as a Symptom in Oncology

Pain as symptom is a more complex which affects a person at all stages of the disease physically, psychosocially and financially. In 2008, the International Association for the Study of Pain (IASP) stated: “for the more than 10 million people worldwide who are diagnosed with some form of cancer each year, pain associated with their condition is a serious concern. The consequences of unrelieved cancer pain are devastating” [1].Cancer pain is a complex symptom which affects person’s life, including activities of daily living, psychological and emotional status and social interactions as well. The prevalence of cancer pain varies widely at different stages of cancer and its treatment (Fig. 1). The estimated pooled prevalence of cancer pain in populations undergoing curative treatment is 39.3% (95% CI 33.3–45.3); 55.0% (95% CI 45.9–64.2) during anticancer treatment; 66.4% (95% CI 58.1–74.7) in advanced, metastatic, or terminal disease and 50.7% (95% CI 37.2–64.1) in studies that included all cancer stages [2]. Pain is one of the most dreaded symptoms in cancer; regrettably, it is often undertreated. Even with the greater availability of pain medications, it continues to be moderate to severe in more than 50% of cancer patients [2]. Of all the patients with advanced stage cancer who experience pain, 70% of pain is associated with the primary cancer, and 20% is associated with cancer treatments and remaining 10% will have pain from other chronic pain syndromes [3]. Of the various pain syndromes, visceral cancers had the highest prevalence of pain followed by head and neck cancer pain and skeletal metastases [4]. In a 10-year prospective study, Zechet et al. [5] reported on localization, etiology and type of pain syndromes. Pain was most often localized to lower back, lumbar spine, sacrum and coccyx (36%) followed by abdominal region (27%), thoracic region (24%) and lower limbs (22%). In 85% of patients, cancer was the most common cause of

pain. Caraceni et al. [6] published a study involving prospective, cross-sectional, international survey of pain specialists and their patients which also incorporated data from Tata Memorial Centre, Mumbai, India. They reported that somatic pain occurred in 39.7% of patients with major pain syndromes comprised of skeletal lesions (41.7%), other types were visceral lesions (28.1%) and those with soft tissue infiltration (27.8%). Karnofsky performance score was <70% in more than 76% of patients. A large majority of patients (92.5%) had one or more type of pain and 20.8% of patients suffered pain due to cancer therapies.

Comprehensive assessment and reassessment of pain is the key to successful cancer pain management [7]. Multidisciplinary approach is the best way to manage cancer pain. In patients undergoing active therapy, the goal of cancer pain management is to provide them with sufficient relief to tolerate the diagnostic and therapeutic procedures required for the treatment. Opioids remain crucial to the management of cancer pain. However, obstacles to global pain relief remain primarily issues of access to clinicians and medications which are scarce in developing countries.

2.1 Barriers to Pain Relief

1. Government and system barriers, such as legislation limiting the availability of or access to opioids [8], or lack of effective policies on pain management and palliative care [9];
2. Physician barriers, such as inadequate education around pain assessment and management, concerns about the risk of respiratory depression or excessive sedation [10] and "opiophobia" [11]; and
3. Patient barriers, such fear of addiction, the belief that "good" patients do not complain about pain, worry that treatment implies the final stages of life and concern about side effects [12, 13].

As per the WHO, over 80% of the world's population is inadequately treated for moderate to severe pain [14]. It is equally important to control symptoms like psychological distress and the entire pain experience other than just pain.

3 Pathophysiology of Cancer Pain

Cancer pain shares the same neuropathophysiological pathways as noncancer pain. The molecular complexity of cancer pain is one of the reason for poor cancer pain control [15]. Cancer pain is often a mixed pain, and it involves inflammatory, neuropathic, ischemic and compressive mechanisms at multiple sites [16]. Most of the knowledge about cancer pain is currently based on preclinical models of cancer-induced bone pain [17]. Inflammatory infiltration of the tumor occurs and various cytokines and inflammatory pain mediators from the cancer cells and from a potential necrotic center in larger tumors are released [18]. There is a direct damage to the sensory nerves by infiltration or compression of tumor cells, or by remodeling in the local microenvironment causing hyperinnervation or denervation of the bone, or stretching of the densely innervated periosteum.

Cancer pain is classified into various types (Table 1).

Cancer pain can be classified as pain due to tumor, cancer treatment or unrelated to it [19]:

- **Tumor-related pain:** Pain may be the major symptom, prompting medical consultation and the diagnosis of cancer. Recurrent pain during the course of illness or after successful therapy has the immediate implication of recurrent disease.
- **Pain due to cancer therapy:** Postsurgery pain like phantom limb pain, postthoracotomy or postmastectomy pain, postchemotherapy pain or pains due to radiation neuropathy are few of the examples.

- **Pain unrelated to cancer:** Patients may have pain due to diabetic neuropathy, postherpetic neuralgia, cardiac pain or joint pain due to osteoarthritis.

Table 1 Classifications of cancer pain

Etiologic classification	• Primarily caused by cancer (e.g., metastatic bone pain) • Treatment of cancer (e.g., postthoracotomy pain, chemotherapy induced peripheral neuropathy, radiation induced mucositis) • Debility (postherpetic neuralgia) • Concurrent pathology (e.g., osteoarthritis)
Pathophysiologic classification	• Nociceptive (somatic, visceral) • Neuropathic • Mixed pathophysiology • Psychogenic
Location of cancer pain syndromes	• Head and neck pain • Chest wall syndromes • Vertebral and radicular pain • Abdominal or pelvic pain • Extremity pain (e.g., brachial plexopathy or bony spread)
Temporal classification	• Acute • Breakthrough • Chronic
Severity-based classification	• Mild • Moderate • Severe

Based on temporal distribution, pain is classified as Acute, breakthrough and chronic pain [19]. Acute pain is a well-defined pain with acute onset, with physical signs and hyperactivity of autonomic nervous system.

Breakthrough pain is a sudden flare-up of pain in patients whose baseline pain is well controlled on a by-the-clock analgesic [20, 21].

Chronic pain is persistence of pain for more than 3 months and is associated with significant changes in personality, lifestyle and functional ability.

4 Evaluation and Grading of Cancer Pain

Clinical practice guidelines developed by the National Comprehensive Cancer Network (NCCN) [22] and American Pain Society (APS) [23] emphasize the essential practice of comprehensive pain assessment. Comprehensive overview of the pain assessment process is shown in Fig. 2.

Core elements of initial assessment [24]:

- A detailed history of pain.
- A psychosocial assessment.
- A physical examination.
- Diagnostic evaluation of common cancer pain syndromes.

• Psychiatric history including current or prior history of substance abuse

Fig. 2 Comprehensive cancer pain assessment

Table 2 Cardinal features of pain assessment

Location	Where does it hurt? Use a body outline chart for precision, which is easy for patients to use. Cancer patients frequently have many pains—elicit a description for each (see Fig. 2).
Quality	What does it feel like? Something like "shooting, burning, pins and needles" helps diagnose a neuropathic component. Describe each separate pain that the patient is experiencing.
Intensity	How bad is it? Use a scoring system. (a) Numerical scale: For example, 0–10 where 10 is the "worst possible pain" (see Fig. 3) (b) Visual analog scale in which a patient indicates pain with a mark on a 100-mm line (horizontal or vertical) delimited by descriptors (none to worst possible to pain). Pain is reported as the measurement, for example, 67 (see Fig. 3) (c) Word scale: Particularly good for concrete thinkers who cannot describe pain in terms of a number (see Fig. 3). (d) Faces scale: Particularly useful for children, the elderly, and those who do not speak your language (see Fig. 3).
Temporal pattern	When does it occur (including impact on sleep)? How long does it last?
Radiation	Where does the pain go?
Exacerbating and relieving factors	What makes it better? What makes it worse? What medications are you taking for the pain (prescription and over the counter)? What effect do they have?
Meaning	What does the pain mean to you? Also what it means to their family. Inquire about the emotional, social and spiritual dimensions.

The evaluation begins with a thorough history of pain and the malignancy and other comorbid conditions. It is also important to take history of the treatment of malignancy.

A critical component for defining the appropriate therapeutic strategy for each individual patient is adequate clinical assessment of pain. Always believe the patient's complaint of pain. Follow the seven cardinal features (Table 2, Fig. 3) of pain assessment [25]:

Pain also has a major impact on quality of life; thus, it is also necessary and essential to evaluate the effects of pain on physical and psychosocial well-being as well the spiritual effects on a patient's life. Since pain is multidimensional which affects the sensory and affective components in addition to intensity, there are many standardized pain questionnaires available that assess pain severity and other dimensions of pain (Brief Pain Inventory, McGill Pain Questionnaire, European Organization for the Research and Treatment of Cancer Quality of Life Questionnaire).

It is very important to ask history of the ongoing oncologic treatment including current and prior chemotherapy, radiation therapy and surgery, as most of the cancer pain is due to the cancer itself and the ongoing cancer therapy helps us to understand the pain pathophysiology to provide better pain management.

Cancer patients with pain usually have symptoms other than pain like fatigue, weakness, cachexia and cognitive deficits (most often due to cancer itself) [26].

Various tools like M. D. Anderson Symptom Inventory (MDASI) or the Edmonton Symptom Assessment System (ESAS) may be used to assess the presence and intensity of symptoms [27, 28].

It is of utmost importance to find out about the other significant illnesses and conditions, as we need to be careful and cautious when prescribing certain pharmacological agents (e.g., NSAIDs in CKD patients) and performing pain interventions (e.g., patient on anticoagulants for deep vein thrombosis).

It is important to undertake a careful medical and neurologic examination, as in one retrospective study they found that two-thirds of the patients had new and often treatable pathology diagnosed as a result of a neurological evaluation [29].

A review of the appropriate diagnostic studies: CT scan, MRI, bone scan and tumor markers often help to differentiate the primary site of the tumor and the metastatic involvement, as well as assess disease progression.

A pre-existing chronic pain experience has been strongly associated with suffering and is important to understand the unique patient experience, which often include religious beliefs and cultural influences, on the expression or treatment of pain [30].

It is very important to individualize the therapeutic approaches and discuss in advance directives with patient and family.

The Edmonton Staging System (EDSS) [27] provides a clinical staging system for cancer pain. The system allows accurate prediction of the outcome of patients with cancer pain. It has an excellent sensitivity (>90%), but poor specificity (<50%) [31]. The cancer pain prognostic scale (CPPS) proposed by Hwang and others [32] is an excellent tool for the accurate prediction of the likelihood of achieving adequate pain relief for patients with moderate to severe cancer within 2 weeks. Both of these tools, the EDSS and the CPPS, are important as well for prognostication of pain management outcomes.

The endpoint of the assessment of the patient is to establish a "pain diagnosis" and individualized pain treatment plan based on mutual agreement of goals.

The "pain diagnosis" should include the etiology and pathophysiology of pain:

- Etiology
  - Cancer
  - Cancer therapy (RT, chemotherapy, or surgery) or procedures
  - Not related to cancer

5 Management of Cancer Pain

The management of cancer pain is often requiring a multidisciplinary approach. Radiotherapy, chemotherapy, hormones, bisphosphonates and surgery are all used to treat and palliate cancers and are directed against the etiology of pain. Most cancer pain management strategies will require [25]:

- A combination of pharmacologic and nonpharmacologic interventions
- Education of the patient, family and all caregivers about the plan
- Ongoing assessment of treatment outcomes.

To provide effective pain relief, the treatment must be customized to suit individual needs. Oncologists should have a working knowledge of pain management. The use of specific pharmacological agents and interventional techniques often require trained medical personnel who have clinical experience in managing cancer pain, which requires referral to specialty pain management centers.

Almost 45%–100% of cancer pain is relieved using an opioid-based analgesic regimen and using the WHO three-step analgesic ladder (Fig. 4) as guidelines [33].

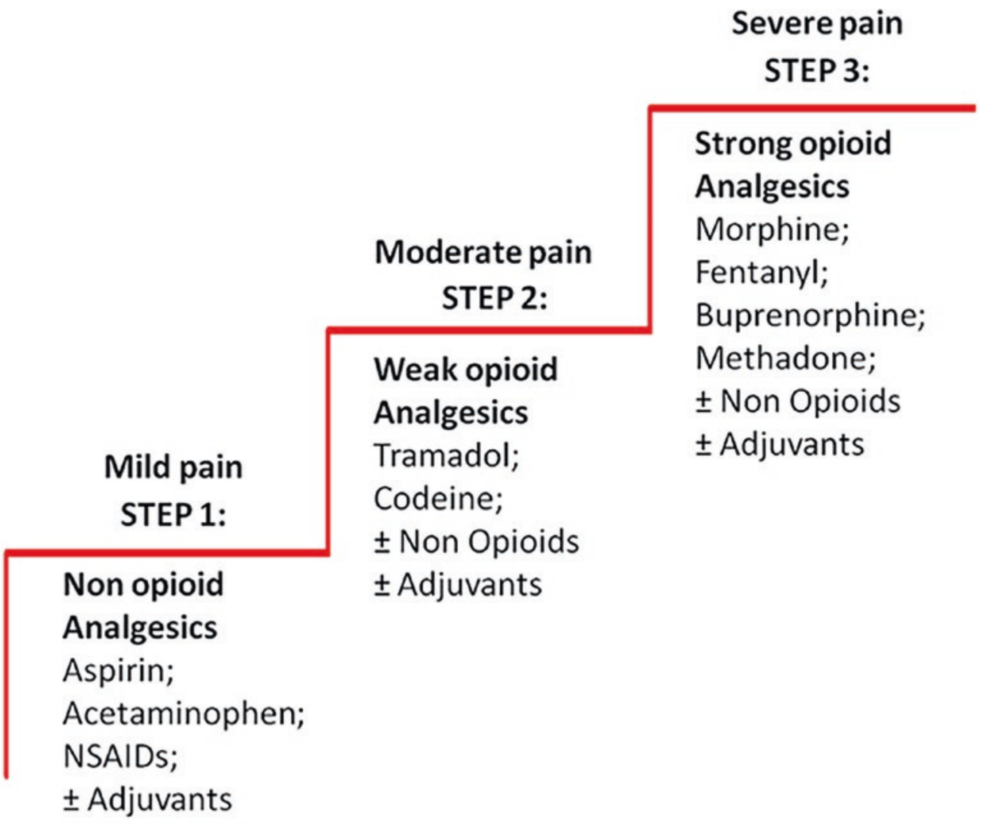
The primary outcome of both the pain physician and the patient should be:

- To achieve a pain-free night
- To ensure pain-free at rest
- To improve a patient's activity of daily living with less discomfort and
- To control breakthrough incident pain (related to physical activity or movement) this is much more difficult to achieve.

Oral analgesic drug therapy is the mainstay for cancer pain management, which has been emphasized by guidelines issued by various organizations.

WHO analgesic ladder: Since 1986, the management of cancer pain had been based on the WHO 3-step analgesic ladder [34]. This simple guideline recommends oral analgesics which can be prescribed as per the severity of pain (mild, moderate, severe) from step one to three [35].

- For mild pain (generally 1 to 3 of 10 on a numerical rating scale), start at step 1.
- For moderate pain (generally 4 to 6 of 10), start at step 2.
- For severe pain (7 to 10 of 10), start at step 3.



Severe pain
STEP 3:
Strong opioid Analgesics
Morphine;
Fentanyl;
Buprenorphine;

Mild pain
STEP 1:
Non opioid Analgesics
Aspirin;
Acetaminophen;
NSAIDs;
± Adjuvants

Fig. 4 WHO three-step analgesic ladder

Analgesic potency gets escalated from nonopioid to weak-to-strong opioid-like oral morphine. Adjuvant drugs can be prescribed at any stage of the treatment.

The key principles include:

- **By the mouth**: Use oral analgesics whenever possible.
- **By the clock**: medications to be given on round the clock basis.
- **By the ladder**: escalate analgesics from nonopioid to weak opioid to strong opioid depending upon the pain severity and response.
- **For the individual:** Individualize the dose which provides a satisfactory pain relief with minimum side effects.
- **With attention to details**: monitoring adherence, side effects and adverse effects of the drugs prescribed.

The pharmacologic therapy includes the following:

- Nonopioid analgesics
- Opioid analgesics
- Adjuvant medications
- Anticancer therapy

6 Nonopioid Analgesics

Paracetamol or nonsteroidal anti-inflammatory drugs (NSAIDs) are used for mild or moderate pain (Table 3). The efficacy of paracetamol and NSAIDs was concluded in a recent systematic, but there is equivocal evidence that the combination of the nonopioid and opioid is more effective than an opioid alone [36]. These drugs are most commonly used orally and their analgesia is limited by a ceiling effect. In patients with high gastrointestinal risk, selective cyclo-oxygenase-2 inhibitor, such as etoricoxib, or a nonselective inhibitor (diclofenac sodium) plus a proton-pump inhibitor, and in high cardiovascular risk, naproxen should be used; NSAIDs should not be used in the presence of both high gastrointestinal and cardiovascular risk [37]. NSAIDs provide effective pain relief in bone metastasis pain. Palliative Radiotherapy is the gold standard for bone pain but NSAIDs are adjuvants to further enhance the pain relief due to their anti-inflammatory mechanism. Combining NSAID to an opioid for severe cancer pain is efficacious, but the risk of long-term adverse effects has not been quantified. There is inadequate literature to support using acetaminophen with stronger opioids [38].

Table 3 Different types of available nonopioid analgesics

Name	Half-life (hours)	Dosing interval	Caution	Max doses (mg/day)
Acetaminophen	2–4	4–6	Hepatotoxicity	4000
Aspirin	3–12	4–6	GI toxicity, allergy, platelet inhibition	6000
Ibuprofen	3–4	4–8	GI and renal toxicity	4200
Naproxen sodium	12	12	GI and renal toxicity	1000
Ketoprofen	2–3	6–8	GI and renal toxicity	300
Indomethacin	4–5	8–12	GI and renal toxicity	150
Diclofenac	2–4	6	GI and renal toxicity	200
Ketorolac	4–6	4–6	GI and renal toxicity	300
Etoricoxib	6–8	12–24	Cardiovascular diseases	120

Table 4 Principles of opioid use

Choose a well-tolerated opioid
Use morphine as drug of choice for moderate to severe pain
Avoid opioids that are difficult to use, e.g., methadone, excess side effects, e.g., codeine
Use round-the-clock dosing
Identify indications for alternative or novel routes of administration
Quantity analgesic response and duration
Review opioid doses regularly until pain is controlled
Identify dose-limiting side effects
Anticipate constipation and psychological side effects
Diagnose opioid resistant pain syndromes
Be aware of the equianalgesic dose of opioids

Table 5 WHO step II opioids for moderate cancer pain in opioid-naive patients

Codeine	Use alone or in combination with paracetamol; doses ≥360 mg per day are not recommended
Tramadol	Use alone or in combination with paracetamol; doses ≥400 mg per day are not recommended

7 Opioid Analgesics

Opioid analgesics are mainstay in the management of cancer pain. During last two decades, there has been a dramatic increase in our knowledge of the sites and mechanism of action of opioids. In contrast to nonopioids, opioid analgesics (pure agonists) do not appear to have ceiling effect, i.e., as the dose is escalated, analgesia also increases and the increment in analgesic is linear to the point of loss of consciousness. Balancing the desirable (pain relief) and undesirable effects (nausea, vomiting, constipation, tolerance) is the challenge (Table 4). The selection of an opioid analgesic is based on the severity of pain needed to be treated based on the WHO three-step analgesic ladder.

Tramadol and codeine are used for treatment of moderate pain as in the WHO analgesic ladder step 2, while morphine, fentanyl, buprenorphine and methadone are used to treat severe pain as in step 3 of the WHO analgesic ladder.

Step II WHO analgesic ladder drugs should be added for inadequate pain control by paracetamol or NSAID (e.g., codeine or tramadol; Table 5) to achieve good pain relief without troublesome adverse effects. Alternatively, low doses of a step III opioid (e.g., morphine) may be used instead of codeine or tramadol. One randomized trial found that low-dose morphine (up to 30 mg daily) reduced pain significantly as compared to codeine (or tramadol) with or without acetaminophen in patients with moderate cancer pain with similar tolerability and an earlier effect [39].

Strong opioids (Table 6) are the mainstay of analgesic therapy in treating severe cancer pain. Clinically meaningful pain relief with tolerable side effects and an overall benefit to quality of life should be the goal of long-term opioid therapy [40].

Although the oral route of administration is advocated, the patients presenting with severe pain who need urgent relief should be treated and titrated with parenteral opioids, usually administered by intravenous (IV) route. If given parenterally, the equivalent dose is one-third of that of the oral medication.

Thus, if a patient in severe pain gets relief with 3 mg of IV morphine, the equianalgesic oral dose is 10 mg per dose and taking 4 h as half-life, the patient needs 60 mg of oral morphine in 24 h. When the pain relief is stable with the above therapy, this can be replaced either with sustained release morphine or transdermal preparations. The breakthrough dose is about the one-sixth or one-tenth 24-h morphine dose. Thus, if the patient needs 60 mg of morphine in 24 h, breakthrough dose will be 10 or 6 mg.

A change in the opioid drug or route of administration to improve therapeutic benefits and minimize harm and increase benefits is termed as opioid rotation or opioid switch.

When opioid requirements are stable, we can advise transdermal fentanyl and transdermal buprenorphine (Table 7). When patients are unable to swallow, patients with poor tolerance to morphine and patients with poor compliance, they are the treatment of choice.

Methadone has often been viewed as an alternative to oral morphine but its specific pharmacokinetic characteristics and a very long and unpredictable half-life [41] require careful individualization of dosing schedules.

The side effects of the opioid analgesics often limit their effective use. The most common side effects are:

- Nausea and vomiting: Use of antiemetic along with the opioid, or switching the opioids helps.
- Constipation: When opioid analgesics are prescribed, a regular bowel regimen including stool softeners with

Table 6 Mainstay strong opioids

Drug	Equianalgesic doses	Half-life	Duration of action (hrs)	Comments
Morphine	10 mg IM/IV/SQ; 20–30 mg PO	2–3 h; 2–3 h	3–4 h; 3–6 h	Standard for comparison for opioids; several routes available; cautious in renal failure
Codeine	200 mg PO	2–4 h	4–6 h	Used for moderate pain
Modified-release morphine	20–30 mg PO	2–3 h	8–12 h	–
Sustained-release morphine	20–30 mg	PO 2–3 h	12–24 h	–
Methadone	10 mg IM/IV/SQ, 20 mg PO	12– 150 h	6–8 h	Patients need increased vigilance for weeks, until steady state; can prolong the QTc interval, and ECG should be checked at doses higher than 100 mg per day
Fentanyl	50–100 μg IV/SQ	7–12 h	1–2 h	Can be administered as a continuous IV or SQ infusion
Fentanyl transdermal system	–	NA	48–72 h per patch	Refer to package insert for equianalgesic dosing guidelines for oral and parenteral medication; not usually recommended for opioid-naive patients in currently available doses; not recommended for acute pain
Transmucosal fentanyl citrate formulations	–	7–12 h	1–2 h	Indicated for the treatment of breakthrough pain

Table 7 Relative analgesic ratios for opioid switching

Opioid	Relative analgesic ratio	Strength of the recommendation for use
Oral morphine to TD buprenorphine[a]	75:1	Weak
Oral morphine to TD fentanyl[b]	100:1	Strong

TD Transdermal

[a] Example: 60 mg oral morphine to 35 μg/h TD buprenorphine (equivalent to 0·8 mg per 24 h)

[b] Example: 60 mg oral morphine to 25 μg/h TD fentanyl (equivalent to 0·6 mg per 24 h)

peristalsis enhancer should be started. Opioid antagonists (e.g., methyl naltrexone) that do not penetrate the blood-brain-barrier are new effective treatment for opioid-induced constipation.

- Sedation: Sedation and drowsiness vary with the drug and dose.
- Respiratory depression: Is rarely a problem because pain stimulates the respiratory center, and tolerance develops to this adverse effect.
- Multifocal myoclonus can occur and is treated by adding clonazepam. Dose reduction of opioid and opioid rotation also helps.

8 Adjuvant Drugs

These are commonly used to (1) provide analgesia for certain types of pain viz. neuropathic pain or somatic bone pain, (2) treat opioid side effects and (3) treat other symptoms associated with pain or to potentiate the analgesia of the drugs in a synergistic manner. These adjuvants are the integral part of WHO three stepladder guidelines, which can be used at any stage of the ladder.

The adjuvant analgesics [40] (Table 8) can be divided into (1) antidepressants, (2) anticonvulsants, (3) corticosteroids, (4) bisphosphonates, (5) anticholinergics and (6) somatostatin analogues.

Other adjuvant drugs such as clonidine, benzodiazepine, neuroleptics and NMDA antagonists (ketamine) are used in the management of neuropathic pain. Use of ketamine infusion has been found to be effective in certain cases of refractory neuropathic pain. The drugs, viz., bisphosphonates compound, radionucleotides, e.g., strontium 89, Samarium 153, have been found to effective in the treatment of pain with multifocal metastatic bone disease. Strontium 89 is indicated in patients with refractory multifocal pain due to osteoblastic lesion, who have a life expectancy greater than 3 months and have sufficient bone marrow reserves.

Table 8 Adjuvant analgesic agents in management of cancer pain

Adjuvants	Examples	Dose (mg)	Remarks
Antidepressants			
• TCA	Amitriptyline	10–25	Neuropathic pain
• SNRIs	Duloxetine	20–40	Better side effects profile than TCAs
• SSRIs	Escitalopram	10–20	Not much evidence
Anticonvulsants	Gabapentin Pregabalin	100–2600 75–600	Neuropathic pain, postsurgical pain
Steroids	Dexamethasone	2–8 mg per day, sometimes up to 20 mg per day	Bone pain, neuropathic pain, lymphedema pain, headache, bowel obstruction
Bisphosphonates	Zoledronate	4 mg every 3–4 weeks	Usually considered first-line treatment; also reduces other adverse skeletal-related events; concern about osteonecrosis of the jaw and renal insufficiency might restrict use
	Pamidronate,	60–90 mg every 2–3 weeks	
	Ibandronate	–	
Anticholinergics	Hyoscine compounds	–	In combination with steroids, used for bowel obstruction
Somatostatin analogues	Octreotide	0.3–0.6 mg per day	In combination with steroids, used for bowel obstruction

TCA Tricyclic antidepressants, *SSRI* Selective serotonin reuptake inhibitor, *SNRI* Selective noradrenaline reuptake inhibitor, *Mg* Milligram

9 Interventional Therapies

Interventional therapies, like nerve blocks, cementoplasty and other techniques, can be useful in the relief of cancer pain. Almost 10%–20% of patients with pain that is poorly responsive to opioids, or where there are intractable side-effects, may benefit from invasive procedures. It should be emphasized that such procedures are not the “fourth step” of the WHO analgesic ladder, but can and should be considered at each step depending on patient preference and need [42]. These procedures should be tried at an earlier stage to have maximal advantage and better quality of life. Intrathecal therapy by pump implant, neurolytic celiac plexus or superior hypogastric or ganglion impar block, spinal neurolysis, vertebroplasty and image-guided tumor ablation are some of the interventional procedures. About 8%–11% patients can benefit substantially from these procedures to reduce the side effects of analgesics. A temporary diagnostic block using a local anesthetic should always precede a neurolytic block. Some cancer pain syndromes are more amenable to neurolytic block, e.g., celiac plexus block for cancer pancreas and paravertebral somatic block for postthoracotomy pain syndrome.

9.1 Peripheral Blocks

9.1.1 Somatic Blocks

Peripheral nerves and plexus can be blocked in a similar manner to temporary perioperative block. Examples include brachial and lumbar plexus blocks. Intercostal blocks are often performed for chest wall pain, and give relief for an average of 3 weeks when phenol is used.

9.1.2 Visceral and Sympathetic Blocks

Visceral and sympathetic blocks are mainly used to control the pain originating from the viscera and sympathetic hyperactivity.

Celiac plexus block: used to relieve upper abdominal and referred back pain caused by malignancy involving the upper abdominal structure (pancreas, stomach, duodenum, liver and gall bladder).

Superior hypogastric plexus block: used to relieve pelvic pain due to malignancy of rectum, vagina, cervix and other pelvic organs.

Stellate ganglion block (cervicothoracic ganglion block): useful for pain in the face, upper neck and hemicranium.

Ganglion impar block: used to treat lower pelvic or perineal pain, coccydynia, troublesome tenesmus and anorectal pain from local malignancy.

9.2 Central Blocks

Intrathecal neurolysis may be used to provide long-lasting analgesia in malignant pelvic or perineal pain syndromes and may be helpful in severe chest or abdominal wall disease.

Phenol or alcohol can be used, with the hyperbaricity of phenol making it useful for perineal or pelvic pain, and the hypobaricity of alcohol lending itself to treatment in the cervical and thoracic levels [42].

9.3 Intrathecal Implantable Pumps

This is indicated when life expectancy is 3–6 months. The epidural or intrathecal catheter is tunneled and connected to an implanted pump which sits in the superolateral quadrant of the buttock or the anterior abdominal wall. Morphine (somatic pain) or Ziconotide are the drugs commonly used through this therapy.

Radiofrequency denervation, spinal cord stimulation and dorsal column stimulation (DCS) have also been successfully used in selected cases.

SVC	Superior vena cava
TLS	Tumor lysis syndrome
TRALI	Transfusion-associated acute lung injury
WHO	World Health Organization

1 Introduction

Critically ill oncology patients have distinct physiologic and pathological characteristics specific to cancer that set them apart from other critically ill patients [1, 2]. They are prone to cancer-specific complications such as drug toxicities and tumor lysis, and are also at a higher risk to develop overwhelming sepsis, opportunistic infections and multi-organ dysfunction due to cancer or cancer treatments. For a positive outcome in oncology critical care, the treating doctors should have a thorough knowledge about the current illness and disease process, along with an understanding of oncology-specific issues [2]. This familiarity about the pathophysiology of various diseases and the host response to disease states, result in better care to the patient [3]. Oncology critical care is no longer considered as futile and currently plays an important role in planning treatment options, including aggressive chemotherapies and aggressive surgeries to an otherwise vulnerable population [4]. The intensive care unit (ICU) currently admits extremely vulnerable patients and yet is able to maintain good quality of life in approximately 50% of all these patients after ICU discharge [4]. This is in large measure due to the advances that have incurred in the area of critical care (Table 1). Apart from usual challenges in the ICU, the oncology critical care is challenging due to few cancer-specific complications as enlisted in Table 2.

Table 1 Changes that incurred in oncology critical care over years

Increase in the number of patients being admitted to ICU for oncology-specific critical care.
Increased administration of chemotherapeutic agents in ICU for oncologic emergencies.
Significant change in practice from invasive ventilation to noninvasive strategies such as noninvasive ventilation (NIV) and high flow oxygen by nasal cannula (HFNC).
Availability of better therapeutic agents and treatment strategies, e.g., newer antimicrobial agents, chemotherapeutic agents.
A significant increase in ICU survival and improved quality of life after ICU discharge.

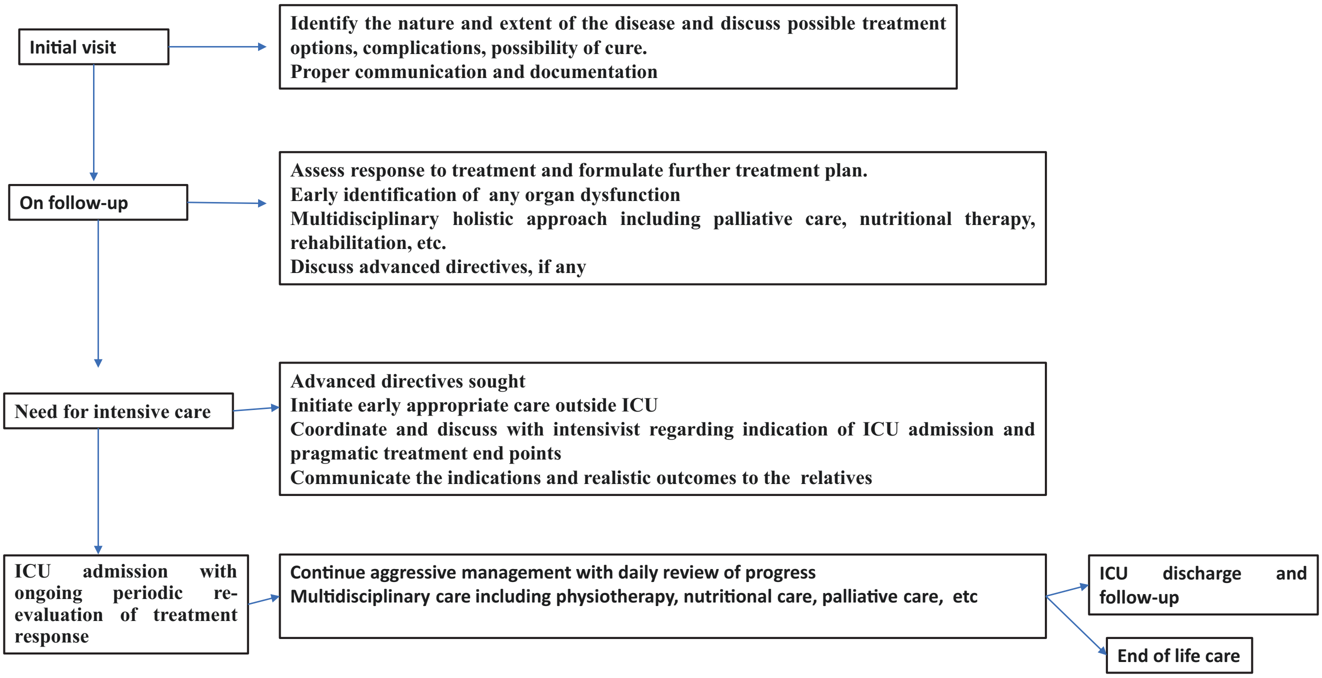
Table 2 Challenges pertinent to oncology critical care

Patients are highly prone to otherwise rare medical emergencies due to a variation form normal immunity, physiology and anatomy such as opportunistic infections, difficult airway, etc.
There is a high incidence of oncologic emergencies such as tumor lysis syndrome (TLS), airway emergencies, metabolic emergencies, neuroemergencies and circulatory complications that require urgent intervention and management.
Specific treatment-related complications such as life-threatening capillary leakage, hypotension and acute respiratory distress are seen in patients receiving chimeric antigen receptor modified T cells (CART), chemotherapy induced pneumonitis and chemotherapy induced organ damage.
Increased incidence of postoperative complications due to extensive and radical surgeries.

2 Integrated Approach to Oncologic Critical Care

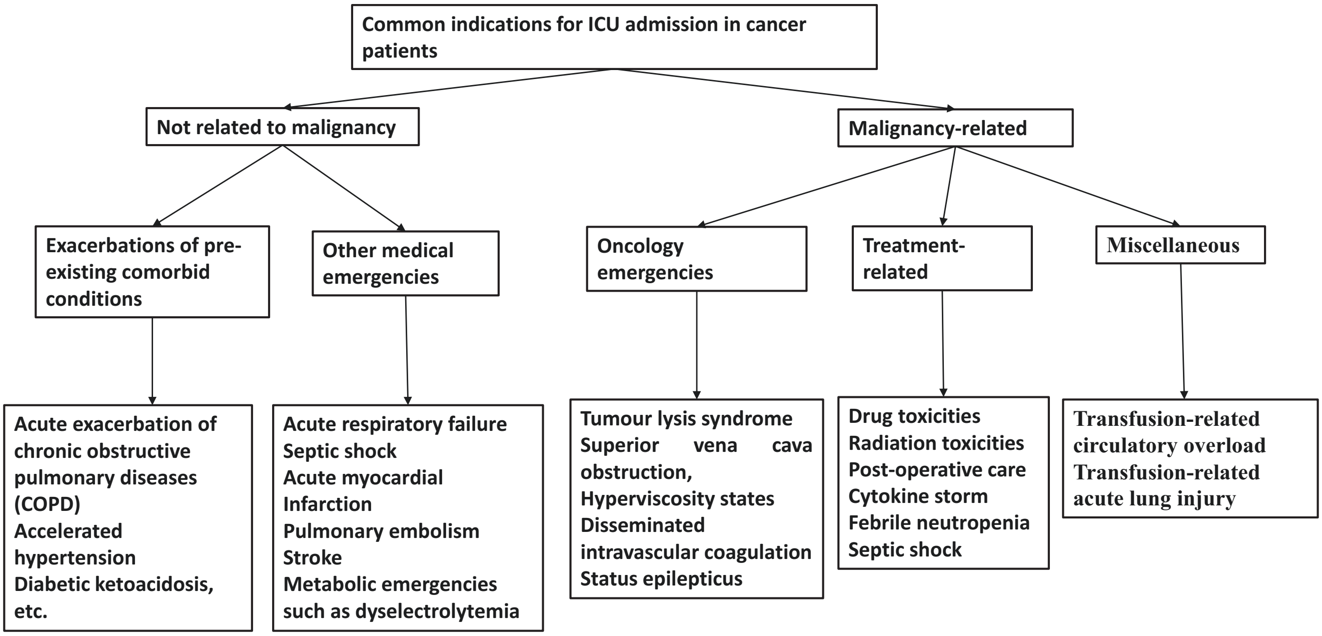
In the ICU, most of the critically ill oncology patients will have multiple comorbidities apart from cancer-specific problems. Therefore, the inputs regarding patient management should be taken from the treating physician (oncologist or oncosurgeon), intensivist and other departments including rehabilitation therapy, nutrition, pain services, palliative care services, etc. [5]. This integrative care should start from the initial hospital visit itself, preferably before any ICU admission. The patient should be evaluated in detail, and the expected course of the disease, the treatment options and expected outcome should be conveyed to the patients and relatives in an empathetic yet realistic manner. After initiation of cancer directed treatment, the response of the disease to the treatment must be evaluated periodically. All further treatment plans should to be formulated based on the treatment response, the symptom relief obtained, the nutritional status, performance score and the necessity of providing further symptom management and comfort care.

When the need for intensive care is anticipated or arises, the parent unit should initiate a discussion with the intensive care team and also with the patient and patient relatives. All patients who are expected to benefit from intensive care may be shifted to the ICU if they are willing for the same. During the stay in ICU, the patient's progress should be assessed daily by the team who has already evaluated the patient. Concerns regarding the patient's treatment and progress should be discussed collectively among the treating team. Several patients admitted to ICU will receive full code management for the initial 3–5 days as a part of a time bound ICU treatment trial [6]. Once the patient improves and no longer requires ICU support, they may be shifted back to the wards in conjunction with the primary team. These patients need to be followed up for identifying and treating complications related to ICU stay including post intensive care syndrome. Figure 1 summarizes a flowchart of integrating care from initial hospital visit to post ICU discharge.



Initial visit
Identify the nature and extent of the disease and discuss possible treatment options, complications, possibility of cure.
Proper communication and documentation
On follow-up
Assess response to treatment and formulate further treatment plan.
Early identification of any organ dysfunction
Multidisciplinary holistic approach including palliative care, nutritional therapy, rehabilitation, etc.
Discuss advanced directives, if any
Need for intensive care
Advanced directives sought
Initiate early appropriate care outside ICU
Coordinate and discuss with intensivist regarding indication of ICU admission and pragmatic treatment end points
Communicate the indications and realistic outcomes to the relatives
ICU admission with ongoing periodic re-evaluation of treatment response
Continue aggressive management with daily review of progress
Multidisciplinary care including physiotherapy, nutritional care, palliative care, etc
ICU discharge and follow-up
End of life care

Fig. 1 Flowchart summarizing the integrated pattern of care in oncology critical care



Common indications for ICU admission in cancer patients
Not related to malignancy
Malignancy-related
Exacerbations of pre-existing comorbid conditions
Other medical emergencies
Oncology emergencies
Treatment-related
Miscellaneous
Acute exacerbation of chronic obstructive pulmonary diseases (COPD)
Accelerated hypertension
Diabetic ketoacidosis, etc.
Acute respiratory failure
Septic shock
Acute myocardial Infarction
Pulmonary embolism
Stroke
Metabolic emergencies such as dyselectrolytemia
Tumour lysis syndrome
Superior vena cava obstruction,
Hyperviscosity states
Disseminated intravascular coagulation
Status epilepticus
Drug toxicities
Radiation toxicities
Post-operative care
Cytokine storm
Febrile neutropenia
Septic shock
Transfusion-related circulatory overload
Transfusion-related acute lung injury

Fig. 2 Common indications for admission in oncology critical care units

3 Admission into Oncology Critical Care Units

Patients will require intensive care for diseases related to or unrelated to the natural course of the underlying malignancy [7] (Fig. 2). Neither clinical judgment nor screening tools can accurately identify the subset of patients who may benefit from ICU care [8–10]. Hence, the policies for admitting oncology patients into critical care units have to be designed locally and are described in Table 3.

The ICU admission policies should be based on the principles of beneficence, nonmaleficence, autonomy and justice [1]. At times, patients are required to be admitted for a time bound trial of ICU care to avoid delay in ICU admis-

Table 3 Admission patterns followed in oncology critical care

Admission type	Implication	Indication
Full code	For full aggressive treatment including all invasive procedures until the disease resolves	Patients in whom complete recovery and a good ICU free survival is anticipated. For example, those with their disease states cured from malignancy, postoperative patients, and those who are treatment naïve—newly diagnosed malignancy with unknown treatment response, etc.
ICU trial	For full aggressive treatment including all invasive procedures for a prespecified time after which the response to treatment is evaluated and further plan is made	Patients in whom the therapeutic response to treatment is uncertain, those who are treatment naïve or those in the initial phases of treatment. Aggressive treatment is provided for 3–5 days and then the patient is re-evaluated and decisions regarding further treatment are made according to the response to the treatment given so far.
Limited ICU Trial	ICU admission with clear instructions regarding management including the treatments to be offered and withheld.	Patients are admitted to ICU for treatments that cannot be provided in ward (e.g., noninvasive ventilation) or those requiring frequent monitoring (pain management after a palliative procedure)
Exceptional ICU admission	ICU admission for the management of otherwise acute and reversible causes	Patients who develop acute illness that is potentially reversible with minimal interventions and care. For example, dyselectrolytemia, glycemic emergencies, etc.
Prophylactic admission	ICU admission for patients who are currently stable but expected to have a rapid deterioration And a narrow therapeutic window between deterioration and clinical management.	Admission for those who are anticipated for tumor lysis syndrome (TLS) anticipated tumor bleeding or in who severe reactions to treatment is anticipated (e.g., CART therapy—see text)
Miscellaneous	ICU admissions not fitting in above criteria	Patients admitted to ICU due to a lack of consensus regarding advanced directives between the intensivist/primary physician/relatives
NO admission	Patients who are unlikely to benefit from ICU admission are often denied admission to ICU.	Patients admitted with advanced malignancy, those who have failed on all possible treatment regimes, moribund patients, etc.

sion. This is also important as a delay in ICU admission is associated with increased mortality. During the ICU stay, while continuing treatment they may be evaluated for treatment response or treatment futility [6] Patients who fail to benefit from the ICU trial or those who further deteriorate despite maximal aggressive medical therapy should be identified early and should be considered for nonescalation of further treatment after detailed discussion between the treating teams of physicians initially and later with the family.

Patients who are predicted not to benefit even from the best supportive care—e.g., those with end-stage disease conditions or those with reduced life expectancy or those with pre-existing poor performance scores—may be denied ICU care and instead shifted to a palliative care setting [4].

4 Management of Critically Ill Oncology Patient Admitted to an ICU

The management of common medical emergencies unrelated to malignancy remains unchanged regardless of the presence or absence of malignancy, e.g., management of myocardial infarction, cardiac failure, acute exacerbation of chronic obstructive pulmonary disease (COPD), etc. Description of the management of these common diseases is out of the scope of this chapter and will not be considered here.

5 Management of Oncologic Emergencies

Oncologic emergencies (metabolic or nonmetabolic) are the leading cause of ICU admission in centers catering to oncology patents. A brief description of the initial management of these is given below.

5.1 Respiratory Failure

Acute respiratory failure (ARF) is the one of the leading cause of ICU admissions for oncology patients. Among patients with hematologic and solid malignancies, approximately 5%–50% of ICU admissions are due to respiratory failure while about 42%–88% of ICU admissions in hematopoietic stem cell transplant recipients are due to respiratory failure. Infections, pulmonary edema, radiation induced lung damage/chemotherapy induced pneumonitis, diffuse alveolar hemorrhage (DAH), pulmonary embolism, disease progression causing respiratory failure, etc. are the common causes of ARF resulting in ICU admission [11].

Majority of the pulmonary infections are due to common bacteria, although opportunistic infections like pulmonary aspergillosis, pneumocystis jirovecii pneumonia, mucormycosis, respiratory viral infection including cytomegalovirus, etc. are also common. Many of these infections eventually progress to acute respiratory distress syndrome (ARDS).

Noninfectious causes of respiratory failure include sepsis, drug induced lung injury, transfusion-associated acute lung injury (TRALI), pulmonary alveolar proteinosis, bronchiolitis obliterans and organizing pneumonia, hemophagocytic lymphohistiocytosis and rarely due to progression of underlying malignancy (Lymphangitis carcinomatosis or pulmonary leukostasis/leukemic infiltration).

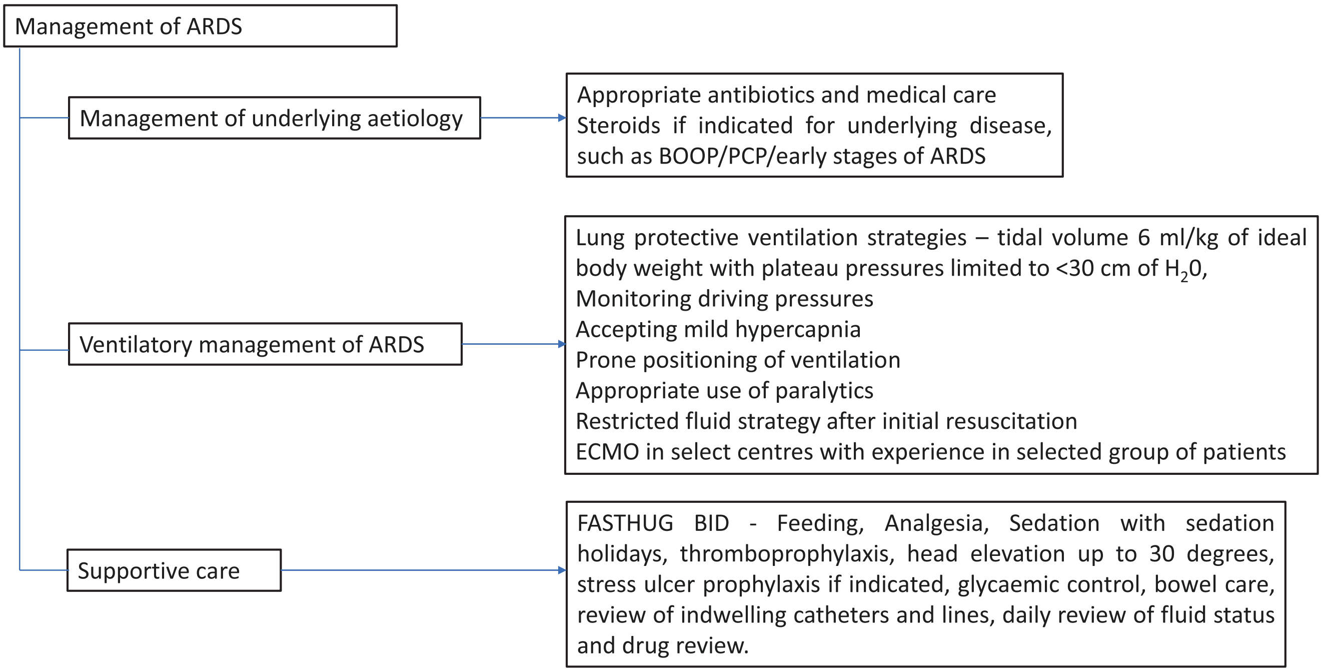
5.1.1 Management of Acute Respiratory Distress Syndrome

Management of acute respiratory failure includes a complex multimodal diagnostic approach, i.e., a clinicoradiological approach assisted by microbiological investigations such as staining, culture, or polymerase chain reaction (PCR) of a lower respiratory tract specimen or lung biopsies, galactomannan assays, etc. [12].

An example of multimodal approach for acute respiratory failure is shown in Fig. 3 [13]. This approach has aided to reduce the mortality rates from 89% to approximately 59%, 63% and 68.5%, respectively, in mild, moderate and severe ARDS [14, 15]. The initial high mortality for ARDS was considered to be the complications of invasive ventilation, and noninvasive ventilation (NIV) was suggested as a tool to tide over the same. However, as the management strategies of invasive ventilation in ARDS improved, the initial enthusiasm for NIV gradually reduced. The overall NIV failure rates are as high as 70%, especially in severely ill patients. Early administration of NIV has not been shown to improve mortality rates in patients with high SOFA score, severe ARDS or associated pulmonary infections [16]. High flow nasal cannula (HFNC) can deliver humidified oxygen at very high flow rates—even up to 60 L/min. These high flow rates help to maintain a positive end-expiratory pressure, aid in alveolar recruitment, improve oxygenation and reduce the work of breathing. Trials have showed a trend toward mortality benefit in Type I respiratory failure patients among immunosuppressed patients and cancer patients when treated with HFNC as compared to NIV [17, 18]. However, these require further validation by adequately powered good quality trials [5, 6]. Extracorporeal membranous oxygenation (ECMO) for ARDS in malignancy requires expertise due to complications such as bleeding and infections [19]. ECMO may thus be considered only in selected group of patients, and in centers with adequate experience in dealing with both ECMO and oncology patients.

5.2 Sepsis

Oncology patients are usually immunosuppressed due to the underlying malignancy or due to an iatrogenic neutropenia (absolute neutrophil count <1500/cc). These patients are prone to overwhelming infection with common pathogens as well as opportunistic pathogens. Severe infections are seen in those with profound neutropenia (absolute count of PMN less than 100) or if the duration of neutropenia extends more than 7 days. International societies have published guidelines of management of febrile neutropenia in ICU and also



Management of ARDS
Management of underlying aetiology
Appropriate antibiotics and medical care
Steroids if indicated for underlying disease, such as BOOP/PCP/early stages of ARDS
Ventilatory management of ARDS
Lung protective ventilation strategies – tidal volume 6 ml/kg of ideal body weight with plateau pressures limited to <30 cm of H_20,
Monitoring driving pressures
Accepting mild hypercapnia
Prone positioning of ventilation
Appropriate use of paralytics
Restricted fluid strategy after initial resuscitation
ECMO in select centres with experience in selected group of patients
Supportive care
FASTHUG BID - Feeding, Analgesia, Sedation with sedation holidays, thromboprophylaxis, head elevation up to 30 degrees, stress ulcer prophylaxis if indicated, glycaemic control, bowel care, review of indwelling catheters and lines, daily review of fluid status and drug review.

Fig. 3 Management of ARDS

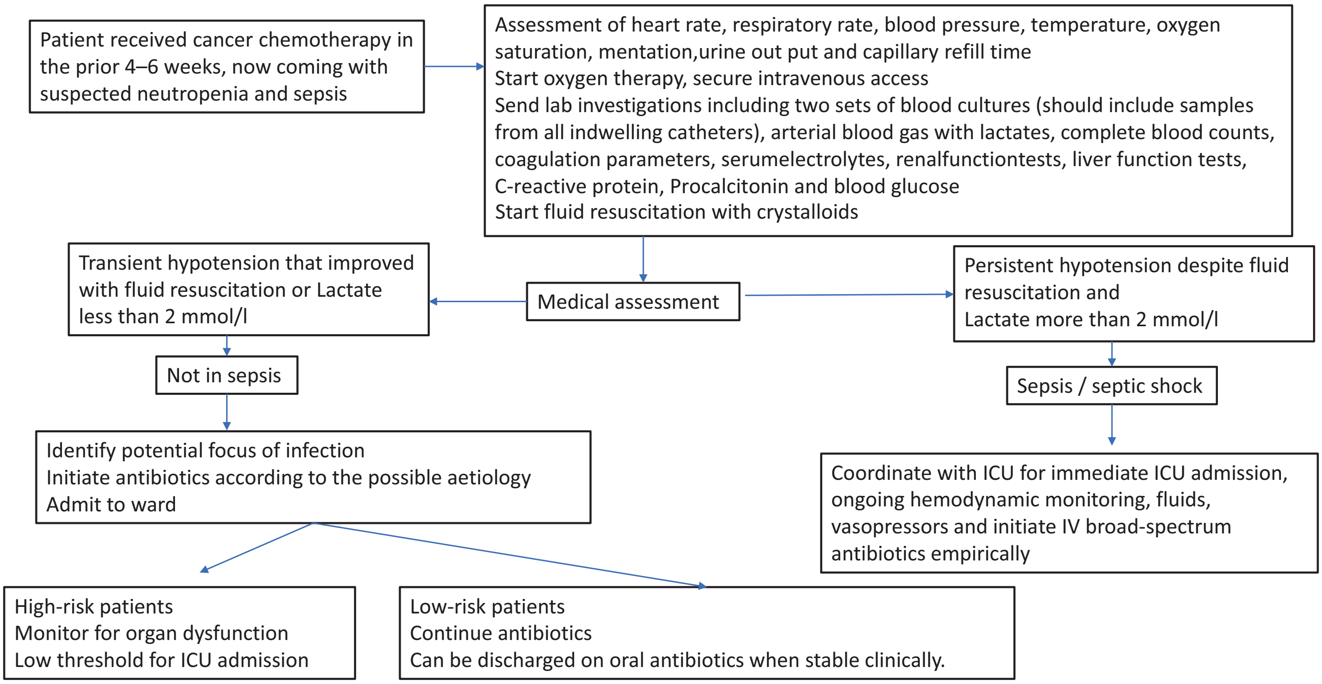
regarding outpatient management of febrile neutropenia [20–22]. Empirical antibiotic treatment for multidrug-resistant (MDR) pathogens will be required for majority of these patients. In patients with hemodynamic instability, additional coverage for gram-positive pathogens and fungal pathogens might also be required.

The pathophysiology of sepsis and septic shock remains the same as in those without cancer. No clinically significant differences have been demonstrated in the macro circulation or the microcirculation. Due to a dysregulated host response to infection, multiorgan dysfunction sets in and multiorgan dysfunction is associated with a worse prognosis than neutropenia or disease progression. The host response to infection is often blunted, preventing early recognition, and patients present with signs and symptoms of infections of the lungs, GI tract, urinary tract or at times as primary bacteremia with source unidentified.

5.2.1 Management of Sepsis in ICU

The management of sepsis in oncology patients is similar to those without malignancy (Fig. 4). It is to be considered as a medical emergency, needs to be identified early and managed with hydration (30 mL/kg crystalloids), ongoing hemodynamic evaluation, hemodynamic support (including management of fluid responsiveness), antibiotics, vasopressors and appropriate source control wherever feasible [23]. In cases of life-threatening emergencies, the presence or suspicion of sepsis or requirement of life support systems should not defer the administration of chemotherapy if otherwise indicated [24]. With the implementation of sepsis bundles, the mortality rate of sepsis has reduced to 40% in oncology patients. Antibiotics should be selected as per the foci of infection, prior antibiotics received, prevailing local antibiogram, possibilities of opportunistic and fungal infections, underlying disease characteristics and pharmacokinetic–pharmacodynamic principles. They should be administered early, after appropriate cultures are sent. The antibiotic therapy may be deescalated later once culture reports are available or if there is a positive treatment response.

In patients with septic shock or organ dysfunction, treatment should be initiated with a broad-spectrum agent such as carbapenem. Polymyxins like colistin and polymyxin B also may be required, as per the available local antibiogram, case history and renal function. Combination therapy with a third or fourth-generation cephalosporin and aminoglycoside or meropenem and a polymyxin may also be used if aerobic gram negative infections are suspected. Coverage for gram-positive organisms needs to be added in patients with hemodynamic instability or as per international guidelines /local institute treatment protocols [21]. Neutropenia, diabetes mellitus, chronic renal failure, indwelling catheters prolonged antibiotics therapy multisite fungal infection or colonization, etc. are considered high risk for invasive fungal infection. Antifungal agents need to be added empirically to such patients and also to patients who fail to improve even after initial appropriate antibiotic therapy. In hemodynamically unstable patients, echinocandins preferred for antifungal therapy. Liposomal amphotericin B is a second-line drug for escalation or used as an initial therapy if the patients were already receiving posaconazole or voriconazole [25].



Patient received cancer chemotherapy in the prior 4–6 weeks, now coming with suspected neutropenia and sepsis
Assessment of heart rate, respiratory rate, blood pressure, temperature, oxygen saturation, mentation,urine out put and capillary refill time
Start oxygen therapy, secure intravenous access
Send lab investigations including two sets of blood cultures (should include samples from all indwelling catheters), arterial blood gas with lactates, complete blood counts, coagulation parameters, serumelectrolytes, renalfunctiontests, liver function tests, C-reactive protein, Procalcitonin and blood glucose
Start fluid resuscitation with crystalloids
Medical assessment
Transient hypotension that improved with fluid resuscitation or Lactate less than 2 mmol/l
Not in sepsis
Identify potential focus of infection
Initiate antibiotics according to the possible aetiology
Admit to ward
High-risk patients
Monitor for organ dysfunction
Low threshold for ICU admission
Low-risk patients
Continue antibiotics
Can be discharged on oral antibiotics when stable clinically.
Persistent hypotension despite fluid resuscitation and
Lactate more than 2 mmol/l
Sepsis / septic shock
Coordinate with ICU for immediate ICU admission, ongoing hemodynamic monitoring, fluids, vasopressors and initiate IV broad-spectrum antibiotics empirically

Fig. 4 Initial assessment and management of sepsis in oncology critical care

5.3 Tumor Lysis Syndrome (TLS)

Tumor lysis syndrome (TLS) is an acute life-threatening emergency in patients with large tumor load, e.g., Burkitt's lymphoma, acute leukemia and rarely a solid tumor.

Tumor lysis may occur spontaneously in rapidly proliferating malignant cells; more commonly, once treatment is initiated, massive cell lysis occurs, releasing large amounts of intracellular phosphorous and potassium into the circulation. Their serum levels increase to dangerously high values and can predispose to life-threatening cardiac arrhythmias. There is also increased release and break down of nucleic acids leading to hyperuricemia which can cause urate nephropathy, cardiac conduction defects and gout. Calcium binds with circulating phosphate resulting in calcium phosphate crystallization in the kidneys and further worsens renal failure and urate nephropathy [26].

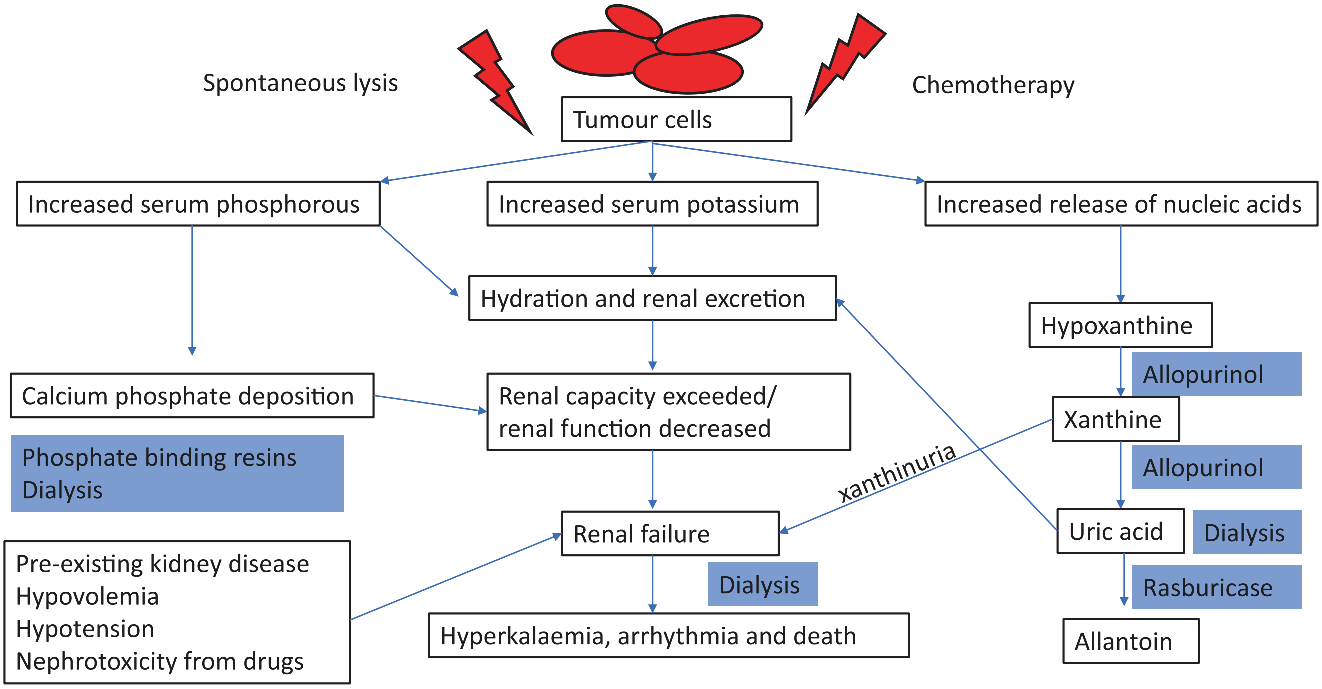
5.3.1 Management of Tumor Lysis Syndrome

TLS is managed by early identification, prophylactic administration of uricosuric agents, phosphate binders and potassium binders. Hydration is started at a rate of 200 mL/kg/day or 2 to 3 L/m^2 of body surface area (BSA) to maintain a urine output of 100 mL/m^2 BSA in high-risk cases. Dialysis may be required in case of life-threatening hyperkalemia or hyperphosphatemia not controlled with medical management (either due to increased production or a decrease in the kidney function), presence of fluid overload, or in cases where underlying comorbid conditions restrict the intake of fluids [26]. Pathophysiology and management of tumor lysis syndrome is described in Fig. 5.

5.4 Dyselectrolytemia

Apart from TLS, patients with malignancy present to ICU with acute dyselectrolytemia including hypercalcemia, hyponatremia, etc. Hypercalcemia occurs in approximately 10%–20% of cancer patients and presents with nonspecific neurological symptoms like confusion, nausea, constipation, lethargy, etc. It is important to identify these complications as it can rapidly progress to coma and death. Hypercalcemia is managed by aggressive rehydration, calcitonin followed by intravenous bisphosphonates, steroids in case of granulomatous disease or rarely dialysis for refractory hypercalcemia.

Symptomatic hyponatremia commonly occurs due to syndrome of inadequate antidiuretic hormone secretion (SIADH), hypovolemia, inadequate oral intake or underlying cardiac or liver dysfunction. Acute symptomatic hyponatremia can also occur due to rapid urinary sodium lose, especially after chemotherapy with cyclophosphamide, cisplatin, etc. Acute hyponatremia is a medical emergency due to acute onset rapid cerebral edema. Hence, for all patients with symptomatic hyponatremia, 2–4 mL/kg of 3% saline should be given as a rapid bolus over 20 min. The dose may be repeated if the patient remains symptomatic and the rise in serum sodium is less than 8–10 mmol/day. Caution should be taken to avoid rapid correction of serum sodium (more



Spontaneous lysis
Chemotherapy
Tumour cells
Increased serum phosphorous
Increased serum potassium
Increased release of nucleic acids
Hydration and renal excretion
Hypoxanthine
Allopurinol
Calcium phosphate deposition
Renal capacity exceeded/
renal function decreased
Xanthine
Phosphate binding resins
Dialysis
Allopurinol
xanthinuria

Pre-existing kidney disease
Hypovolemia
Hypotension
Nephrotoxicity from drugs
Dialysis
Rasburicase
Hyperkalaemia, arrhythmia and death
Allantoin

Fig. 5 Pathophysiology and management of tumor lysis syndrome

than 8–10 mmol/day), as rapid corrections may result in osmotic demyelination syndromes [27, 28].

5.5 Airway Emergencies

Compromise of the airway can occur due to the local spread of the disease or secondary to mediastinal compression of the superior vena cava (SVC syndrome). Patients present with respiratory distress, hemoptysis, cough, etc. and may have audible stridor. Evaluation of the cause of airway compromise should comprise of a computerized tomography scan as it may aid in differentiating the causes of acute dyspnea, and helps to formulate a treatment plan by predicting the possible complications during intubation. Direct visualization of the airway by rigid or flexible bronchoscopy can also be attempted as it may serve both as a diagnostic and therapeutic tool. Management in such cases requires interventions to secure the airway including intubation if needed and definitive management of the local cause by radiation, or chemotherapy depending upon the nature of malignancy. In the case of thymic tumors, respiratory distress can be due to a direct tracheal compression well as due to myasthenia. In such cases, thymectomy can relieve the airway compression and cure myasthenia in a subset of patients [29]. Involvement of the tracheal or bronchial lumen by tumor may necessitate tracheobronchial stenting or debulking. This will need an expert multidisciplinary team of pulmonologists, thoracic surgeons and anesthesiologists for best outcomes.

5.6 Cardiac Dysfunction

Cardiac dysfunction can result from the direct involvement of cancer on the heart, pericardium and great vessels or due to the cardiotoxicity of the medicines used in cancer treatment. Anthracyclines like doxorubicin, monoclonal antibodies like trastuzumab, etc. are well known for their cardiac side effect profile. Patients develop arrhythmias or new ECG changes such as QTc prolongation, and present with breathlessness, or cardiogenic shock. Radiation-associated cardiotoxicity usually present with coronary artery disease, valvular dysfunction, dilated cardiomyopathy, conduction defects and diastolic heart failure. Radiation pericarditis occurs acutely on starting treatment or may present as late as 6 months to 1 year after treatment. Medications such as Dasatinib or surgical procedures such as pneumonectomy can cause pulmonary hypertension (PH) and right heart failure. Cardiac tamponade can be caused by massive pericardial effusions. The patients present with chest pain, light headedness, palpitations, dyspnea, orthopnea and dry cough. Bedside echocardiography will reveal collapse of right sided cardiac chambers during diastole. Cardiac failure and pulmonary hypertension are managed in same way as that of noncancer patients with noninvasive ventilation, diuretics, vasodilators and inotropes. Management of pericarditis or tamponade according to the etiology at times needs surgical interventions such as draining a tamponade or pericardiotomy [30, 31].

5.7 Acute Abdomen

Abdominal malignancies can present as subacute intestinal obstruction, intestinal obstruction, or at times as a surgical emergency due to bowel perforation and peritonitis. Infiltration or obstruction of the gall bladder or biliary tract by tumor can cause biliary obstruction, cholangitis and jaundice. Tumour infiltration into major vessels may cause massive hemorrhage and present as hemorrhagic shock. Obstruction to the urinary outflow at the level of the ureters or bladder can cause hydroureteronephrosis, acute kidney injury, acidosis and hypercalcemia. Patients who have received radiation to the pelvis can present later with radiation induced strictures of ureters causing post renal acute kidney injury (AKI), metabolic acidosis and pulmonary edema. The management of acute abdomen requires a case based multimodal approach involving the surgeons, intensivists, interventional radiologists and other specialties including nephrologists for dialysis as per the situation [32].

5.8 Emergencies of the Central Nervous System

Malignancy of the central nervous system (primary and secondary) can present with signs of raised intra cranial pressure such as altered sensorium or seizures. This is a medical emergency and often requires urgent surgical decompression along with medical management. Temporary measures to reduce the intra cranial pressure include anti epileptics, osmotherapy with mannitol or hypertonic saline, administration of corticosteroids, intubation, sedation and paralysis while maintaining normothermia, normoxia and normoglycemia, and avoiding hyper- or hypocarbia.

Acute onset paraplegia may result from epidural or bony metastasis causing spinal cord compression from primaries in lung, breast, prostate, etc. or in cases of multiple myeloma, lymphoma, etc. Patients usually present with symptoms such as pain, motor weakness, sensory symptoms, bowel and bladder involvement, etc. Early suspicion, diagnosis and immediate administration of glucocorticoids, surgery, radiotherapy and systemic chemotherapy in patients with chemosensitive tumors are important to prevent permanent nerve damage.

These patients are also at high risk of other CNS emergencies such as status epilepticus, venous sinus thrombosis, ischemic stroke, cerebral hemorrhage, etc. Management includes prompt diagnosis of the etiology and early treatment [33].

5.9 Adrenal Crisis or Adrenal Insufficiency

Acute adrenal insufficiency can occur due to the replacement of the glandular tissue by neoplastic tissue, due to surgical excision of both glands or at times due to hemorrhage into the adrenals in severe sepsis. Clinical features include nausea vomiting, diarrhea, vague abdominal or flank pain, confusion and vasopressor-resistant hypotension. A high degree of suspicion and supplementation with daily physiologic doses of glucocorticoids after confirming the diagnosis is the main stay of management [34].

6 Postoperative Care in Oncology

Surgeries in oncology patients are most often complex surgeries that involve extensive tissue dissection resulting in fluid shifts and third space loss, electrolyte imbalance, cardiac arrhythmias, impaired glucose control, hypothermia, etc. During the postoperative period, these patients are prone to complications such as bleeding, respiratory failure, malnutrition, venous thrombosis, etc. These patients require more aggressive postoperative monitoring apart from the routine postoperative care such as care till complete recovery from anesthesia, optimizing pain medications and complications such as shivering or postoperative nausea and vomiting [7].

7 Chemotherapy in ICU

Chemotherapeutic agents are extremely toxic drugs requiring specialized knowledge in preparing and administering the drugs. These drugs are now increasingly being used in the ICU to treat or prevent life-threatening malignancy-related emergencies such as hyperleukocytosis, hemophagocytic lymphohistiocytosis (HLH), tumor lysis syndrome, etc. The ICU team should be cautious while administering chemotherapeutic agents and the recommendations regarding dilution, volume, infusion rate, etc. should be followed. In case of any drug reactions, drug toxicities, or drug extravasations, the drug infusion should be stopped immediately and help from oncohematology should be sought [24].

8 Infection Control in ICU

Nosocomial infection commonly affects oncology patients due to their immunosuppression and the rates can be as high as 40%. These carry a huge implication in terms of cost of treatment, morbidity, mortality and length of stay in ICU and hospital. Hence, a systematic approach to reduce these infections is required. Simple measures like maintaining hand hygiene have been proved to be effective in reducing infection rates in hospital. All hospitals now adhere to the "five moments of hand washing" as suggested by World Health Organization (WHO) [35]. Apart from hand hygiene, many bundles (evidence-based group of interventions, each with a high grade of evidence in itself, when performed together adds on to produce a cumulative benefit) have been devised to reduce hospital acquired infections. These infection control bundles are summarized in Table 4 [36, 37].

Table 4 Common bundles in ICU for infection control [35–37]

Ventilator-associated pneumonia bundle	Head end elevation of bed Daily interruption of sedation and spontaneous breathing trials Aspiration of subglottic secretions Peptic ulcer prophylaxis in high-risk patients Deep vein thrombosis prophylaxis
Catheter-related blood stream infections bundle	Maintaining good hand hygiene practices Strict aseptic precautions during line insertion Use of chlorhexidine for skin antisepsis Preference of subclavian and jugular sites over femoral sites Daily review of indwelling catheters and prompt removal of unnecessary lines
Catheter-associated urinary tract infection bundle	Avoid unnecessary urinary catheterizations Catheterize in aseptic precautions Daily care of urinary catheter and remove if not required.

9 Nutrition in Oncology Critical Care

Most of the cancer patients will be malnourished due to reduced oral intake and cachexia of malignancy and complications of treatment. Malnutrition is further aggravated by infections, inflammation, stress, etc. resulting in poor patient outcomes. Therefore, it is imperative that all patients should be assessed for malnutrition with available screening tools. Patient generated subjective global assessment is a simple and inexpensive way for nutritional screening among vulnerable patients and can be utilized at the bedside [38]. Other screening tools like Nutritional Risk Screening 2002 (NRS 2002), the malnutrition universal screening tool (MUST) mini nutritional assessment (MNA) and the malnutrition screening tool (MST) may be utilized as a rapid screening tool, although its use has not been validated in cancer patients. Guidelines recommend the use of performance scales such as the ECOG, or Karnofsky in conjunction with biomarkers such as serum C-reactive protein (CRP) and albumin DEXA (dual X-ray absorptiometry) or bioimpedance analysis (BIA) to assess the nutritional reserve muscle mass and fat for nutritional assessment in high-risk patients [39].

Table 5 Indications of total parenteral nutrition in ICU

Absolute contraindication to enteral feeding	Intestinal obstruction or perforation, necrotizing enterocolitis Worsening hemodynamic instability Mesenteric ischemia
Malfunctioning gut	High output enterocutaneous fistulas Paralytic ileus Massive bowel resection
Inadequate enteral feeding	Patients at a high nutritional risk with anticipated delay in attaining nutritional goals by 7 days Not attaining nutritional goals even after 2 weeks

Regarding feeding, enteral feeding should be initiated early during the ICU stay as it is cheap, safe and continued preferentially as long as it is tolerated. Parenteral nutrition is to be considered in those who are at a high risk of malnutrition and carry contraindications for enteral feeding. Parenteral nutrition is indicated only in a select population in the ICU as described in Table 5 [40]. Even in patients with anorexia, parenteral nutrition has not shown any benefit and priority should always be given to the enteral route if its functioning. Diet fortification with the so called immunonutrition in cancer patients though it seems attractive and physiological is not supported by evidence. Just as any patient with malnutrition these patients are at high risk for refeeding syndrome and needs to be closely monitored for, once the nutrition is initiated [41].

9.1 Recommendations for the Use of Parenteral Nutrition as Put Forward by the American Society for Parenteral and Enteral Nutrition (ASPEN) [42]

1. In cases where there is a contraindication to enteral route or the patient has persistent intolerance to feeds or in cases where they lack adequate bowel function to maintain or restore nutrition status.
2. After 7 days, in adequately nourished patients who are not able to meet at least 50% of the calculated requirements by enteral route.
3. Within 3–5 days in patients at high risk for malnutrition and are expected not to meet the nutritional goals by enteral route.
4. Immediately for patients with moderate or severe malnutrition and enteral nutrition is inadequate.
5. Preoperatively in severely malnourished patients who have intolerance to enteral nutrition.
6. Postoperative for severely malnourished patients who are expected not to tolerate enteral nutrition in 7 days.
7. In patients with advanced disease but having an expected survival of 2–3 months and oral intake or enteral nutrition is not feasible.

10 Outcomes of Critically Ill Cancer Patients

Patients with solid tumors seldom require ICU admission for medical reasons and the most common cause for ICU admission in these groups is for elective postoperative care. However, if they require admission due to medical complications, they have exceedingly high mortality rates compared to normal people [43].

Oncologic emergencies are common in those with hematological malignancy. The common indication for such admissions includes life-threatening medical conditions such as oncologic emergencies, infections or organ dysfunction. They generally tend to have a higher disease severity scores (simplified acute physiology score [SAPS II] or sequential organ failure assessment [SOFA] score) and a higher mortality rate as compared to the general population [44].

Patients who have underwent a Bone marrow transplant (BMT) have high ICU and in hospital mortality, despite a steady decline in mortality rates. Common indications for ICU admission include acute respiratory failure, sepsis, cardiac dysfunction, neurologic disorders, bleeding diathesis, etc. BMT patients requiring mechanical ventilation still have an ICU mortality rate of 80% that further worsens with worsening organ dysfunction. Factors affecting the prognosis of critically ill patients admitted to an ICU are listed in Table 6.

Table 6 Prognostic factors for critically ill oncology patients

Negative	Positive	Neutral
Extremes of age Respiratory failure requiring mechanical ventilation Delay of >2 h in starting appropriate empirical antibiotics Multiple Organ Dysfunction Score >2 organ involvement Higher Apache/ SOFA scores Invasive aspergillosis Poor response of cancer to chemotherapy Poor performance score prior to ICU admission—Karnofsky score <70 or higher Eastern Cooperative Oncology Group (ECOG) scale 3–4	Indication for ICU admission being primary postoperative care Disease in remission Good performance status prior to hospital admission Acute onset of critical illness (<7 days) Absence of fungal infection Absence of comorbidities Reversible cause for ICU admission	Type of tumor (solid vs. hematological) neutropenia, metastatic nature of disease, and prior ICU admission

11 Palliative Care in ICU

In palliative care the primary attempt will be attending to symptom management, empathetic and realistic communication about disease, possible treatment and outcomes and support for both patient and family throughout the course of illness. This is a holistic approach to improve the quality of life of patients and their families, by early identification, meticulous assessment and addressing unmet needs such as pain and other physical, psychosocial and spiritual problems [45]. Palliative care is associated with better control of symptoms, better utilization of resources including ICU stay, increased satisfaction for patient and family and reduced moral stress on the physician, thus minimizing burnout. Examples for palliative care include (but not limited to) addressing pain, thirst, anxiety, dyspnea, etc. The barriers for palliative care should be minimized by effective and realistic communication, discussing advance directives (if present). Palliative care should not be confused with end-of-life care and should be offered to all patients in ICU, especially to those with less than 6 months of anticipated survival at ICU admission, either as an integral part of ICU care or as a part of multidisciplinary care [46].

12 End-of-Life Care (EOLC) in ICU

Ideally only those patients who have a reasonable chance of cure or palliation from their disease or symptoms should be admitted to a critical care unit. However, many a times, patients with advanced disease or those with advanced directives will also be admitted to the ICU for a time-limited full code trial. Although seemingly straightforward, the identification of treatment futility is often vague, delayed and an area of conflict. Unnecessary prolongation of treatment created conflict of interests, increases patient suffering and leads to wastage of resources including manpower. Hence, all attempts should be made to identify futility of care in patients at high risk, being admitted for an ICU trial. If futility is observed, it should be conveyed to the primary team and relatives. An open empathetic communication with relatives and is required both to voice and listen opinions, while avoiding conflict. Care should be taken to avoid confusing terms such as withdrawal of support, mercy killing, etc. [47]. EOLC discussions require time and patience and repeated discussions. Each session must be documented properly to maintain transparency.

Once EOLC is decided, the site of care should be decided, with preference given to patient comfort. Further care to the patient should include avoidance of further aggressive interventions as they increase the sufferings of the patient and maintaining adequate patient comfort. The treatment orders should be reviewed, retaining only medications for symptom control. Unnecessary monitoring should be avoided and close relatives may be permitted to remain by the bedside. Patients should be regular assessed regarding the adequacy of symptom control. The spiritual care should also be taken care, and bereavement support to the family members should be offered to cope with their personal issues [48].

13 Summary

Intensive care in oncology has evolved over decades and is currently a rewarding profession. Properly selected cancer patients admitted to the ICU have survival rates and quality of life identical to their noncancer counterparts. Early identification of sepsis and organ dysfunction along with the use of potent antimicrobial therapies and noninvasive diagnostic strategies for organ dysfunction are some of the factors responsible for the reduction in mortality rates. We need to develop score that identifies those who may benefit from early ICU admission. The strategies used to avoid intubation (like NIV and HFNC) need further evaluation before accepting as an alternative for mechanical ventilation. End-of-life care and palliative care are also integral parts of intensive care and should be offered to all eligible patients. For better outcome of these patients, a multidisciplinary team including intensivist, oncologist and palliative care specialist is essential.

Vascular Access

Sajid S. Qureshi and Nizamudheen M. Pareekutty

Abbreviations

CR-BSI	Catheter-related bloodstream infection
CVAD	Central venous access device
DTTP	Differential time to positivity
IJV	Internal jugular vein
IVC	Inferior vena cava
PICC	Peripherally inserted central catheter
PVAD	Peripheral VAD
SVC	Superior vena cava
TIVAD	Totally implantable venous access device
VAD	Venous access device

1 Introduction

Venous access represents a vital component in the management of malignancy where patients require surgery, systemic cytotoxic chemotherapy, nutritional support, antibiotics, and intravenous hydration. They are equally necessary in advanced cancers for chronic treatment and palliative measures. Peripheral veins are frequently used for venous access. However, they are not sufficient in several patients with cancer where infusate is of high volume, concentrated or incompatible; therefore, central venous access is necessary. In this chapter, we discuss the types of devices, the insertion techniques, catheter care, and complications related to venous access.

2 Classification of Venous Access Devices

Venous access devices (VAD) are broadly classified into peripheral and central devices. Peripheral VAD (PVAD) are 35–52 mm long Teflon cannulas with various diameters inserted into superficial veins of the arms or sometimes lower limbs in children. They are the most commonly used VAD in clinical practice. They are easy to insert and maintain and are suitable only for short-term use. With countless cannulation and subsequent thrombosis or infection, the loss of peripheral veins presents a problem, especially in cancer patients. The need for a constant search for patent peripheral veins is a reason for pain and anxiety for the patients; consequently, not preferred in many situations in oncology.

The central VADs (CVAD) after insertion have the tip of the catheter at the cavo-atrial junction, the lower third of superior vena cava (SVC), atrium, or upper portion of inferior vena cava (IVC). CVADs are classified into four principal types.

1. Nontunneled catheters are used for short-term continuous venous access (up to three weeks) when peripheral lines are not present or not sufficient for the purpose as in major surgical procedure or the intensive care unit. They are 20–30 cm long polyurethane catheters with a single lumen or multiple lumens. They are safe only for hospitalized patients.
2. Tunneled catheters are used when continuous and long-term venous access (>3 months) is needed. Tunneled catheters are made of silicone. They commonly exit externally on the chest and are inserted into the internal jugular vein (IJV) or subclavian vein. Some of these catheters carry Dacron anchoring cuff providing more stability and prevents accidental removal by pulling [1]. The cuff induces an inflammatory reaction within the tunnel leading to fibrosis and catheter fixation. Tunneling reduces the infection rate and prolongs the life of the catheter [2, 3]. Hickman, Broviac, and Mahurkar catheters are examples of tunneled catheters.

3. Totally implantable venous access devices (TIVADs) or “chemoports” or simply “ports” are catheters with a chamber attached at one end. The chamber is implanted in a subcutaneous pocket, and the attached catheter is passed through a tunnel and inserted into a central vein, usually IJV or subclavian vein. The chamber is accessed via a specific needle passed through intact skin. They have a lower incidence of catheter-related bloodstream infection compared to other tunneled and nontunneled catheters. Most ports have a single lumen, and they are suitable for long-term intermittent chemotherapy especially in patients with solid tumors. Ports allow no visible tubes outside; they are ideal especially in children as they allow better mobility without the apprehension of accidental removal of catheter.
4. Peripherally inserted central catheters (PICC) are nontunneled central catheters inserted through a peripheral vein of the arm. They are made of silicone or polyurethane and are 50–60 cm long. The tip of the PICC is advanced to reach SVC or right atrium. They are suitable for intermittent use for up to one year. They have a narrow lumen and are more likely to get thrombosis and occlusion due to narrow lumen and reduced flow rate [4]. Catheter migration due to arm movement is likely to produce endothelial damage, cardiac perforation, and rarely arrhythmias [5–7].

3 Valved Catheters

Valved catheters or Groshong catheters carry a slit-like opening on one side of the catheter tip which functions as a valve. The tunneled, nontunneled, or TIVAD can be provided with a valved tip. Force is required to open the valve, and hence positive pressure infusion is required. The valve-like action prevents entry of blood into the catheter tip while allowing the infusate to flow out of the catheter; hence, reduce the chance of infection and thrombosis. However, this has not been proven in a controlled trial. It also eliminates the need for heparin locks and frequent flushing [8].

4 Choosing the Ideal Catheter

There are barely any evidence-based guidelines available on choosing the right access site and the right catheter. Recently, the choosing wisely campaigns recommend the use of peripheral lines whenever feasible and remove invasive catheters as early as possible [9, 10]. The situations in which central venous access is recommended are [11, 12].

1. Peripheral venous access is not available.
2. Prolonged venous access is called for.
3. Multiple lumen infusions are needed.
4. The infusions are not compatible with peripheral lines, like parenteral nutrition containing glucose concentration of more than 10%, amino acid concentration of more than 5%, pH <5 or >9, osmolarity >500 mOsm/L vasopressors, and certain chemotherapy agents with vesicant character.
5. Hemodialysis or plasmapheresis is required.
6. Hemodynamic monitoring of central venous pressure and pulmonary arterial pressure is indicated.

5 Choice of CVAD

There are no randomized trials available for choosing an appropriate device for an individual patient. It is a combined decision by the physician, nurse, and patient considering factors such as duration of treatment, frequency of venous access, the volume of infusate, patient age, patient’s preference, and the ability of the patient’s caregivers to take care of the device.

Nontunneled catheters are used in hospitalized patients for short-term use when peripheral lines cannot be used or they are not available. They are generally used during major surgeries and in intensive-care units. Tunneled VADs are used in patients who need prolonged continuous administration of chemotherapy, antibiotics, parenteral feeding, and blood products and require frequent blood sampling. Tunneled catheters remain the preferred options in patients with hematological malignancies undergoing induction chemotherapy or bone marrow transplantation.

TIVAD are ideal for children in particular and also in adults where long-term intermittent access with infrequent infusion is required as in solid tumors. Those patients who do not want to have any tubing seen outside are offered chemoports that are completely hidden under the skin. PICCs are more suitable for outpatient-based treatment in ambulatory patients with solid tumors.

6 Preoperative Assessment

Comprehensive preoperative assessment including medical history, clinical examination, laboratory investigations, and radiological evaluations is mandatory. Skeletal deformity, scar, obesity, or previous surgery at the insertion site should be recognized beforehand. Preprocedure ultrasound helps in identifying deep vein thrombosis and anatomic variations [13].

Coagulopathy, thrombocytopenia, and neutropenia should be recognized before the procedure and optimized.

7 Technique of Insertion

The insertion of a PVAD is straight forward and generally performed as a bedside procedure. However, the insertion of CVAD is more demanding and can be associated with potential complications especially in inexperienced hands. The technique of insertion of CVAD is discussed here.

Informed consent should be obtained from the patient. The nature of the procedure, need, and potential complications like pneumothorax and bleeding should be explained. The potential need for secondary procedures like chest tube insertion in case of injury should be discussed. Trendelenburg (head low) position is utilized to facilitate adequate venous dilatation and avoid an air embolism. However, hemodynamically unstable patients may not tolerate this position. Routine preoperative antibiotics have not shown benefit; however, institutional protocols for antibiotic prophylaxis should be followed [14]. The patient should be monitored for cardiac rhythm and oxygen saturation throughout the surgery.

CVAD are usually inserted into the IJV or subclavian vein employing a percutaneous approach. The femoral vein is not a favored site due to the high risk of infection in this site [15]. With the introduction of the Seldinger technique for vascular access in 1952, interventional medicine was revolutionized [16]. With the availability of peel away dilator introducer in the 1970s, open surgical vein cannulation is no longer required for venous catheterization. These developments have reduced the complexity of central venous access and helped to perform central venous catheterization as an outpatient or bedside procedure. However, open technique with a venous cut down is still practiced in cases with intraoperative difficulty and in select situations in children.

Nontunneled catheters can be placed at the bed side; however, tunneled catheters and chemoports are inserted in the operating room. The procedure should be performed with strict sterile precautions under local anesthesia with or without sedation or general anesthesia particularly in children and uncooperative patients.

Skin is infiltrated with 1% lignocaine around the site of needle insertion, site of catheter exit, and the tunnel connecting them. Ultrasound guidance helps for the identification of the vein and cannulation under vision. An ultrasound probe is used to locate the vein, and the needle is guided through the skin and into the vessel. Ultrasound guidance reduces the number of unsuccessful attempts and complications and reduces the duration of the procedure [17–21].

When using the landmark method, IJV is accessed between the medial and lateral head of the sternomastoid muscle and subclavian vein is accessed 1 cm below the junction of medial and middle third of the clavicle (Fig. 1). The introducer needle is inserted with negative pressure until venous blood is aspirated. Sometimes there is a risk of piercing the posterior wall of the vein producing a hematoma or even arterial puncture. This complication can be avoided by advancing the needle under image guidance. Once venous blood is aspirated, advancing the needle is stopped, the ultrasound probe is handed over to the assistant surgeon or the staff nurse and the needle is stabilized using the left hand of the operator. The syringe is carefully removed and the guidewire is threaded through the needle hub into the vein. The intravenous position of the guidewire is confirmed with ultrasound, and the introducer needle is removed. Arrhythmia produced by the advancement of the guidewire till the heart is traditionally used as an indication of the correct positioning of the needle; however, we do not consider it as necessary or advisable when the guidewire position can be confirmed using ultrasound.

Sometimes the guidewire may fail to pass into the vein during the introduction. Several reasons have been thought for this as, displacement of the needle out of the vein, hitting the posterior wall of the vein, kinking of the wire within the vein, and coiling against venous junctions. If resistance is experienced, the advancement of the guidewire is instantly stopped, and the needle position is reconfirmed by ultrasound. A minor change in needle direction to make a more parallel angle with the vein sometimes helps to avoid the guidewire striking the posterior wall of the vein. If the resistance persists, the guidewire is withdrawn, the needle position is confirmed by aspiration and the guidewire is reintroduced. Exceptionally, if guide wire fails to pass despite all efforts, one will have to resort to an open method to identify the vein for catheterization. We routinely implement fluoroscopy to confirm the position of the guidewire at this stage though objective evidence is lacking in this practice.

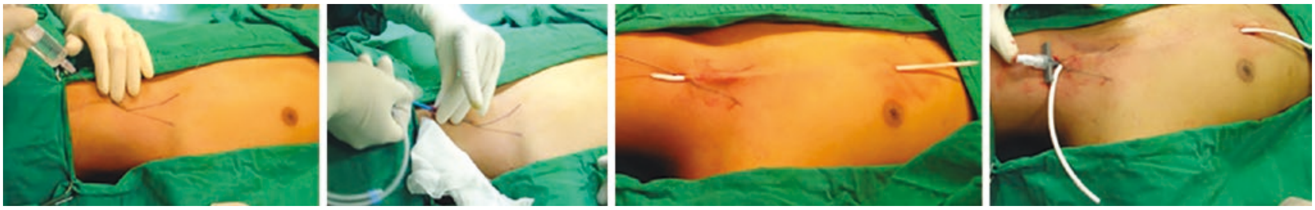

Fig. 1 Sequential clinical images showing the insertion of tunneled central venous access device. The needle is inserted at the apex of the triangle formed by the two heads of sternomastoid muscle. The needle tip is at 45° and directed toward the ipsilateral nipple

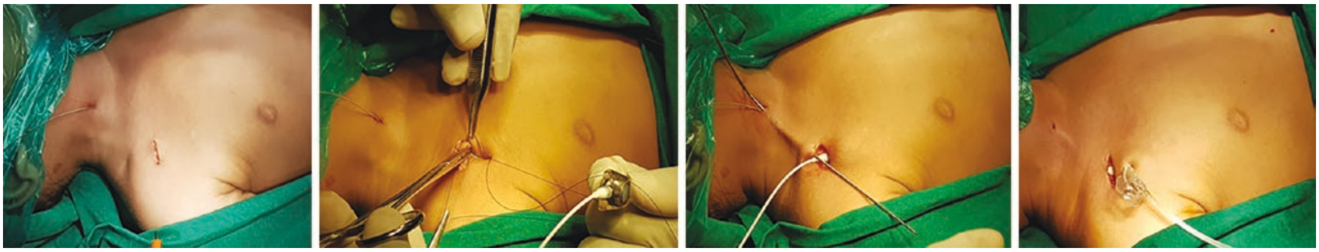

Fig. 2 Sequential clinical images showing the insertion of totally implantable venous access device. The subcutaneous pocket is made in the infraclavicular region, and the chamber is secured with sutures incorporating the pectoral muscles

Once the guidewire is introduced, a small stab incision is made against the wire to increase the opening for the introduction of the dilator. In the case of TIVAD, the attention is directed towards the creation of subcutaneous space for implantation of the chamber. Most commonly the chamber of TIVAD is placed in a subcutaneous plane at the ipsilateral infraclavicular area while the exit site of the tunneled catheter is planned at the inframammary crease between the nipple and sternal border (Fig. 2). However, other areas like supraclavicular fossa, upper back, inner arm, and contralateral infraclavicular area can be chosen depending on the patient's choice, location of the tumor, the field of adjuvant radiation, and local tissue conditions.

An incision is made two fingerbreadths below the clavicle just adequate to introduce the chamber of TIVAD and a subcutaneous space is created. Anchoring sutures are placed with polypropylene, or polydioxanone sutures and parachuting method is used to secure the port chamber firmly on the pectoral fascia and muscle. For the tunneled catheter, the catheter exit site is identified and a small stab incision is made using a scalpel. The tunneling is done to connect the chamber of the port or the catheter exit site to the site of venous access and the catheter is pulled and placed into the tunnel so that in case of the cuffed catheter, the cuff reaches approximately 2.5 cm from the exit site. The length of the catheter is trimmed before insertion in such a way that the tip reaches one centimeter below the sternal angle.

Once the tunnel is constructed, the peel away dilator/introducer is inserted into the vein until the hub touches the skin. Frequent wiggling of the guidewire during the introduction helps to confirm the position of the guidewire and avoid false tracking. After the complete introduction of the dilator, the trocar is removed. Trendelenburg's position is maintained to avoid air embolism. The catheter is placed into the dilator and using thumb it is pushed into the vein. Constant finger pressure is maintained to avoid whiplashing of the catheter out of the dilator. While the thumb exerts pressure on the catheter, the sheath is peeled away and the catheter is inserted completely into the vein.

The Huber needle is introduced into the chamber and the backflow of blood is confirmed and a heparin lock solution is injected. The parachute sutures are tied to secure the chamber and avoid malposition or flipping. Skin sutures on the chamber insertion site are knotted such that the knots do not fall over the chamber. Particular care is observed when skin suture is placed on the accession site to avoid inadvertently taking the wall of the catheter in the suture.

8 Catheter Tip Position

The ideal site for catheter tip placement is continuing controversy. The catheter tip is traditionally placed in the SVC (Fig. 3). However, the catheter tip is liable to migrate to the cavo-atrial junction or right atrium during placement due to excess length or later due to catheter movement. The literature describes unique sets of complications for intracardiac placement as well as intracaval placement of the catheter. Rare complications described specific to intracardiac placement of the catheter tip are dysrhythmia, cardiac perforation, and cardiac tamponade [22–24]. Complications more commonly associated with placement within the vena cava are central venous perforation, hydropneumothorax, hydromediastinum, and venous thrombosis [25–27].

Placement of catheter tip in the upper part of SVC results in an increased incidence of thrombosis compared to placement in the lower SVC or at the cavo-atrial junction [28]. Dialysis catheters placed in the right atrium function better than those placed in the SVC [29, 30]. Unpublished data in pediatric patients using TIVADs for chemotherapy in our center show a higher incidence of catheter thrombosis of 1.99 per 1000 catheter days when the catheter tip was placed in the SVC compared to 1.26 per 1000 catheter days when catheter tip was placed below the cavoatrial junction. In our study, 71 patients had a catheter tip placed in the SVC, and 128 occupied the right atrium.

Traditionally, a postoperative chest radiograph is used for ascertaining the catheter tip position. The angle of the right main bronchus and trachea corresponds to the upper border of SVC and is usually visible on the radiograph [31] Many centers utilize routine intraoperative fluoroscopy to confirm catheter tip position. Recently, ultrasound assessment from right supraclavicular fossa using a micro convex probe is found to be an effective method to visualize catheter tip in the lower SVC and pulmonary artery in a pilot study [32].

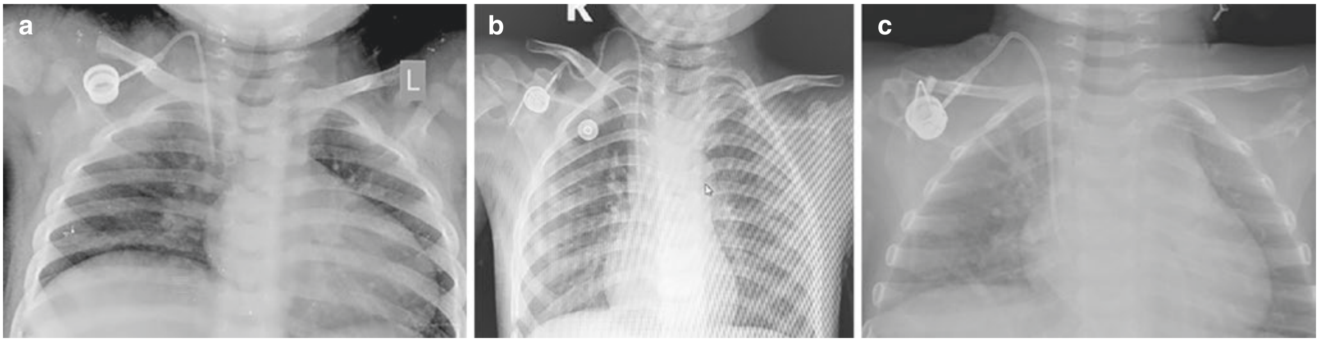

Fig. 3 Chest radiograph showing the catheter tip position in the superior vena cava (**a**), cavoatrial junction (**b**) and below the cavoatrial junction (**c**)

9 Catheter Care

Vascular access devices are flushed and aspirated for blood using a syringe not less than 10 ml capacity (to prevent developing excess pressure within the catheter lumen causing catheter damage) to assess catheter function before each infusion. After use, the catheter is flushed to remove the infusate from the catheter lumen to prevent clogging, and the catheter damage from incompatible medications. Dextrose or components of parenteral nutrition should be meticulously flushed away as they provide nutrients for biofilm formation [33] Flushing using commercially available prefilled syringes helps reduce the incidence of catheter-related bloodstream infection (CR-BSI) [34, 35] compared to intravenous saline preparations [36, 37].

The catheter site should be cleaned and dressings changed every five days when the ports are being used. The access needle should not be left in situ for more than one week. When the port is not used for a long period, flushing of the port with 10 mL of 0.9% saline and locking with heparin saline or 0.9% sodium chloride solution once a month is recommended to prevent catheter block. Randomized controlled trial comparing heparin with 0.9% sodium chloride shows that occlusion rates and toxicity do not differ between the groups [38]. Use of antibiotic lock for prevention of catheter infection is now advocated routinely.

In the case of catheter blocks which are a common problem, the patients need to be treated in the catheter clinic by physicians or trained nurses with a saline injection and aspiration technique. If this does not succeed, urokinase or alteplase injection may help to relieve the block. The vast majority of the catheters can be salvaged with these techniques.

10 Complications Associated with VAD

10.1 Complications of PVAD

The frequent complications associated with PVAD are thrombophlebitis, extravasation injury, hematoma, and bruising [39] Other rarer complications reported are skin necrosis, compartment syndrome, bacteremia, venous embolism, and aneurysm formation [40–42]. Most complications related to PVADs can be reduced by preventing cannulation of veins in the lower extremity, minimizing catheter movement by properly securing, placing the smallest suitable catheter size for the purpose, and removing the catheter as soon as possible [43, 44].

10.2 Complications of CVAD

Serious complications are rare in clinical practice and most are case reports and were reported more than two decades back. The complication of CVAD can be classified into two categories, and they are early complications (occurring intraoperatively or in the initial postoperative period) and late complications.

10.3 Early Insertion-Related Complications

Pneumothorax is a common and serious immediate complication related to central venous access [45, 46]. The most important variable associated with pneumothorax is the operator experience; catheter inserted by a physician with experience of more than 50 prior insertions is half as likely to result in a mechanical complication compared to those by a physician with experience of less than 50 [47]. Subclavian access is more likely to result in pneumothorax compared to IJV cannulation and ultrasound-guided approach to venous access and fluoroscopy guidance to confirm the position of the guidewire within the SVC significantly reduce the incidence [48, 49]. Patients should be observed after the procedure and a routine chest radiograph should be obtained at two hours to rule out pneumothorax or hemothorax. Therapeutic options for iatrogenic pneumothorax include emergency pigtail insertion or a chest tube placement along with administration of oxygen. Asymptomatic, small pneumothorax, in stable patients without preexisting lung disease can be observed and managed conservatively.

Arterial puncture is the most common mechanical complication related to CVAD [50, 51]. The carotid artery, subclavian artery, or femoral artery can be punctured inadvertently. Early recognition of the injury and withdrawal of the access needle and nonocclusive compression of the artery prevents severe bleeding and hematoma. If the artery is dilated or inadvertently catheterized, a vascular repair is indicated and consultation with a vascular surgeon should be sought. In severe cases, injury can lead to arterial thrombosis, stroke, or even death if not acted promptly.

Air embolism occurs when the catheter or the access needle is left open to the atmosphere. It is a dangerous complication and can be lethal. Trendelenburg position and adequate hydration reduce the incidence of serious air embolism. The patient suffers from acute onset dyspnea, cough, chest pain, and collapse if significant air enters the circulation. Left lateral decubitus and Trendelenburg position help to trap air in the right ventricle. 100% oxygen helps in early absorption of air [52].

Ventricular arrhythmias and bundle branch block are recognized complications. During the procedure, the entry of metallic guidewire in the right atrium causes arrhythmias, but it is usually limited [53]. Persistent symptomatic arrhythmia is rare, but if present, the catheter has to be repositioned or removed. Catheter malposition into the subclavian vein or brachiocephalic vein requires reinsertion or re-fixing for adequate function.

10.4 Late Complications

Late complications can be segregated into infectious complications and mechanical complications. They are bloodstream infection, pocket infection, thrombosis, catheter dysfunction, catheter rupture, migration or embolization, pinch-off syndrome, SVC erosion and perforation, cardiac perforation and tamponade, extravasations, and port inversion [54–58]

10.4.1 Infection

Catheter-related infections are classified into three: exit site infection, tunnel infection, or systemic infection (CR-BSI). Most exit site infections and tunnel infections are caused by *Staphylococcus aur*eus. It is manifested by local inflammation, erythema with or without purulent discharge. Most cases are not associated with bacteremia. They can be treated with antibiotics and catheter removal is necessary only in cases that do not respond to antibacterial therapy [59, 60] Implementing sterile technique during insertion, skin antisepsis during catheter use and maintenance, use of antibacterial catheter, and antibacterial catheter lock solution help to reduce the infectious complications.

Systemic infection (CR-BSI) is a more serious condition. They arise either from the spread of the infection from the exit site or the contaminated catheter hub. It is often a challenge to diagnose CR-BSI in clinical practice. They are more common among nontunneled central catheters compared to tunneled ones, PICC and TIVAD and ranges from 1.1 to 2.7 per 1000 catheter days [2] Unpublished data from our center shows that among 203 pediatric patients who received TIVAD, the rate of infection was 0.15/1000 catheter days. Differential time to positivity (DTTP) is a reliable diagnostic tool for identifying CR-BSI. Blood is collected from the CVAD as well as peripheral blood. If the blood from CVAD shows positive growth at least 2 h before the peripheral blood, diagnosis of CR-BSI is confirmed. Empirical antibiotics are initiated after culture samples are obtained. On diagnosis of CR-BSI, nontunneled catheters should be removed, whereas an attempt may be done to preserve tunneled catheters or TIVAD with appropriate antibiotics based on blood cultures and antibiotic lock therapy, provided patient's health condition remains stable.

10.4.2 Mechanical Complications

Catheter thrombosis is the most common complication, and it is due to clots, lipid aggregates, drugs, or contrast agents. Appropriate flushing and locking the catheter as discussed above keep the incidence of catheter block low. In case of irreversible catheter block exchange over the guidewire or removal becomes necessary.

Tip migration occurs due to increased intrathoracic pressure when the catheter is placed inappropriately high in the SVC. It can be prevented by proper positioning. Pinch off syndrome is the compression of the catheter between the first rib and clavicle especially in the case of the catheter in the subclavian vein and usually happens after blind placement through the infraclavicular route. This results in catheter occlusion, malfunction, damage, or fracture. Catheter rupture is a rare complication, and the ruptured segment needs to be retrieved from the pulmonary vessel using interventional radiological procedures.

Damage to the external part of VAD or erosion of the tissue over the catheter chamber happens due to inadequate nursing care and is usually preventable. Catheter dislocation of the tunneled catheter can be prevented by positioning the cuff at least 2.5 cm for the insertion site and that of a nontunneled catheter by proper stabilization. Flipping of the catheter chamber of TIVAD results in malfunction and can be avoided by proper fixation. Cardiac perforation and tamponade are very rare complications of central venous use [61].

11 Special Concerns of CVAD in Pediatrics

Prolonged central venous access is particularly important to children where repeated search for peripheral veins and cannulation is a cause for pain and anxiety for the children as well as the parents and even health care workers. As discussed above, the friendliest option for kids is TIVAD as there is no tubing outside, do not hinder bathing and playing and they require minimal maintenance to keep the device patent. However, in the case of hematologic cancers notably when bone marrow transplantation is planned, a Broviac catheter is preferred.

The insertion of CVAD is more challenging in children due to the small caliber vein, especially in neonates. In select cases with difficulty, an open method with a venous cutdown is considered [62]. Infectious complications are found to be higher in children especially below 2 years [63–65] though the incidence is generally low.

12 Summary

- Central venous access is preferred over peripheral access when prolonged venous access and high volume, concentrated, or incompatible infusion is required.
- CVAD include tunneled catheters, nontunneled catheters, TIVAD and PICC and the choice depends on type and volume of infusate, duration and frequency of treatment, age and choice of the patient.
- Nontunneled central catheters can be inserted at the bedside, whereas tunneled catheters and TIVAD are inserted in the operating room under controlled conditions.
- Insertion-related complications are infrequent with CVAD and is further reduced by the physician experience and use of ultrasound-guided insertion technique.
- Long-term complications of CVAD include infectious and mechanical complications, and they can be reduced by improvising the technique of insertion, improving the quality of catheter care by utilizing dedicated and trained nurses, and equipping the patient's caregivers with knowledge about catheter care.
- Young children suffer infectious complications from CVAD, though the incidence generally remains low.

Comorbidities in the Cancer Patient

Aruna Alahari Dhir, Sandeep P. Tandon,
Sheela Prashant Sawant, Maheema A. Bhaskar,
Anuprita Dilip Daddi, and Aparna Iyer

Abbreviations

ADT	androgen-deprivation therapy
CABG	Coronary artery bypass graft
CAD	Coronary artery disease
CI	Confidence interval
CVD	Cardiovascular diseases
CVD-IP	Collagen vascular disease-associated interstitial pneumonia
DM	Diabetes mellitus
HM	Hematological malignancies
HT	Hypertension
IGF	Insulin-like growth factor
IGRA	Interferon-gamma release assay
IPF	Idiopathic pulmonary fibrosis
IRR	Incidence rate ratio
LTBI	Latent tuberculosis infection
PCI	Percutaneous coronary intervention
RP	Radiation pneumonitis
TB	Tuberculosis
TST	Tuberculin skin test
UIP	Usual interstitial pneumonia
VEGF	Vascular endothelial growth factor

1 Introduction

Comorbidity is a long-term health condition affecting a patient in addition to the index disease. With changing demographics there are increasing number of people over the age of 60 years [1]. With improved life expectancy incidence of both cancer and comorbidities of noncommunicable types are likely to increase. Comorbidities can impact the cancer stage at diagnosis. This impact varies considerably by cancer type, individual comorbid condition and overall comorbidity burden [2]. Presence of co morbidities may affect the decisions related to treatment of cancer or tolerance to cancer treatment, and thus, they may impact cancer outcomes [3]. Comorbidities may pose competing risks for morbidity and mortality in patients with cancer and could be a major confounder in clinical trials [1]. It is observed that cancer patients with higher rates of comorbidity have 1.1 to 5.8-fold higher mortality risk [4]. The risk of major toxicity and hospitalization due to chemotherapy is increased in cancer patients with comorbidities [5–7].

Comorbidity is a multidimensional variable and several scoring indices have been developed to measure comorbidity. Some of the indices are Charlson comorbidity index, Cumulative Illness Rating Scale, Kaplan–Feinsten Index, National Institute on Aging/National Cancer Institute comorbidity index, Adult Comorbidity Evaluation-27 and the Elixhauser method [8–13]. The prevalence of measured comorbidity will vary depending on the measure of comorbidity used, the study population and the cancer type [14]. There is lack of consensus about the best approach to measuring comorbidity burden in cancer patients and the choice of measure may vary depending on the study question, population studied and data available [14].

In patients aged 65 years or older, four of ten patients with cancer had at least one other chronic condition recorded and 15% had two or more as per data from Medicare beneficiaries in the United States. Cardiovascular disease, obesity and metabolic disease, mental health problems, chronic obstructive pulmonary disease and musculoskeletal conditions were the most common chronic conditions recorded in these patients [15]. India faces the dual burden of chronic noncommunicable diseases and communicable diseases [16]. In India, cardiovascular diseases (coronary heart disease, stroke and hypertension) contribute to 45% of all noncommunicable diseases and deaths, followed by chronic respiratory dis-

ease (22%), cancer (12%) and diabetes (3%) [17]. Among communicable diseases in India, tuberculosis contributes the largest number of new cases annually compared to any other country in the world [16]. In a study of breast cancer patients from India 75% of the comorbid conditions were chronic diseases such as hypertension (21.8%), chronic obstructive pulmonary disease (19.9%), rheumatoid arthritis (18.6%) and diabetes mellitus (16.7%) [18].

2 Cardiovascular Diseases

Cardiovascular diseases (CVD) are a leading cause of mortality globally, accounting for 31% of all deaths, followed by cancers, respiratory diseases and diabetes [19]. CVDs are also the leading cause of mortality in India [20]. As per the Global Burden of Disease study, estimate of age-standardized CVD death rate of 272 per 100,000 population in India is higher than the global average of 235 per 100,000 population [21]. With aging population and increased longevity due to advances in cancer therapeutics, the overlap of CVD and cancer is likely to increase [22, 23].

Modifiable risk factors like obesity, diabetes mellitus (DM), hypertension (HT), physical inactivity, diet and tobacco use are common risk factors for both cancer and CVD [24–28]. Obesity, diabetes mellitus, hypertension, CVD and cancer have a complex relationship mediated by several factors such as hormones (sex hormones, insulin and insulin-like growth factor [IGF]), proinflammatory cytokines and adipokines (interleukin 6, tumor necrosis factor alpha, leptin, resistin), angiogenic factors and oxidative stress [29–34]. Obesity has been linked to esophageal, pancreatic, liver, colorectal, postmenopausal breast, endometrial and kidney cancer [35]. Type 2 DM and HT are also linked with certain cancers [25, 36]. Several studies have examined the impact of antidiabetic and cardiovascular medications on cancer incidence (insulins, antihypertensive drugs, aspirin) and on cancer outcomes (metformin and statins) [37–42]. Metformin has been shown to decrease cancer incidence and increase in cancer specific survival in some studies [41].

Coronary artery disease (CAD) is the most common cardiovascular disease. The aim of treatment in patients with CAD is to control symptoms and prevent progression into acute coronary syndrome or infarction [43]. In addition to medical treatment (beta blockers, statins, antiplatelet and angiotensin converting enzyme inhibitors), some patients may require coronary revascularization. The options include percutaneous coronary intervention (PCI) without stent, PCI with bare metal stent or with drug-eluting stent and coronary artery bypass graft (CABG) with or without extracorporeal circulation [44]. In patients in whom coronary revascularization is indicated, the severity of the cardiac disease, the stage of the malignancy and the general condition of the patient should be taken into consideration while choosing the method of revascularization. PCI is preferred if the malignancy is aggressive or widespread. In cancer patients with thrombocytopenia who are planned for PCI, appropriate antiplatelet and heparin dose should be used to avoid bleeding complications [45]. In indicated cases, CABG is a good option only when the malignancy is potentially curable [45]. Cardiac risk factors including hypertension, diabetes, dyslipidemia should be managed optimally [46]. A thorough clinical evaluation should be done to determine the baseline cardiovascular risk as per standard guidelines in all patients receiving cancer directed treatment [47].

Some cancer therapies are also linked with cardiovascular injury, increasing CVD susceptibility via the multiple-hit hypothesis [48]. A wide range of chemotherapy agents have been associated with cardiotoxicity (Table 1). The most frequent cardiotoxicity is asymptomatic or symptomatic left ventricular dysfunction [49]. Other cardio toxic effects include hypertension [50], thromboembolic disease [51], pericardial disease [52], arrhythmias [53] and myocardial ischemia [54]. Radiation therapy where treatment field involves the heart can also lead to coronary artery disease and fibrotic changes of the valves, pericardium and myocardium [55, 56]. These patients may present years or decades after exposure to radiation treatment. With increased longevity due to modern cancer therapeutics, cancer survivors are being exposed to potential comorbidities due to nononcologic side effects of anticancer therapy [57].

In patients receiving treatment for cancer and in cancer survivors, early detection of cancer directed treatment-induced cardiovascular injury, accurate diagnosis and management of cardio-toxic events may improve long-term cardiac outcomes [58]. Early detection of cardiac injury may facilitate early therapeutic measures [59]. Implementation of appropriate monitoring plans as per potential cardiovascular risk are recommended by many guidelines [47]. Cardio oncology is evolving as an important subspecialty which aims is to assist in the overall cardiac care of cancer patients from the initial assessment to survivorship through an integrated approach [60].

Table 1 Systemic anticancer drug-induced cardiotoxic effects [49–53]

Type of cardiovascular toxicity	Drugs
Left ventricular dysfunction	*Anthracyclines/analogues*—Doxorubicin, Epirubicin, Mitoxantrone *Alkylating agents*—Cyclophosphamide, Ifosfamide *Antimicrotubule agents*—Docetaxel *HER 2 receptor Mab*[a]—Trastuzumab *VEGF A Mab* [a]—Bevacizumab *Small molecule TKI* [a]—Sunitinib *Proteasome inhibitors*[a]—Bortezomib, carfilzomib *Immune checkpoint inhibitors*—Nivolumab, Pembrolizumab, Ipilimumab
Myocardial ischemia	*Pyrimidine analogues*—Capecitabine, 5 Fluorouracil *Antimicrotubule agents*—Paclitaxel, Docetaxel, *Alkylating agent*—Cisplatin *VEGF A Mab*[a]—Bevacizumab, *Small molecule TKI*[a]—Erlotinib
Hypertension	*VEGF inhibitors*[a]—Bevacizumab, *Small molecule TKIs*[a]—Sunitinib, Sorafenib, Pazopanib. *Alkylating agent*—Cisplatin *Proteasome inhibitor*—carfilzomib
Pulmonary hypertension	*Small molecule TKI*[a]—Dasatinib
Venous thromboembolism	*Alkylating agent*—Cisplatin *Angiogenesis inhibitors*—Thalidomide, Lenalidomide *VEGF A Mab*[a]—Bevacizumab
Arrhythmias	
Bradycardia	*Antimicrotubule agent*—Paclitaxel *Angiogenesis inhibitor*—Thalidomide
QT prolongation	*Arsenic Trioxide* *Small molecule TKIs*[a]—Lapatinib, sunitinib, Crizotinib, dasatinib, nilotinib, Ribociclib
Supraventricular tachyarrhythmias	*Small molecule TKIs*[a]—Ibrutinib, Ponatinib, Sorafenib *Proteasome inhibitor*[a]—Carfilzomib *Anthracyclines* *Alkylating agent*—Cyclophosphamide *Pyrimidine analogue*—Capecitabine

TKI tyrosine kinase inhibitor, *Mab* monoclonal antibody

[a] Targeted therapy

3 Hypertension

Hypertension is a common chronic disease and modifiable risk factor for CVD, cerebrovascular diseases and chronic kidney disease. As per 2010 data, 31.1% of the world's adults are hypertensive, 28.5% in high-income countries and 31.5% in low- and middle-income countries [61]. About 33% urban and 25% rural Indians are hypertensive [62]. In India, hypertension is the leading noncommunicable disease and attributing for nearly 10% of all deaths [21]. HT has been reported to be the most common comorbidity in patients with cancer accounting for 37% of all comorbidities [63]. New-onset hypertension, regardless of severity, was observed in about one-third of cancer patients with various types of solid tumors [64]. The prevalence of hypertension and cancer both increases with aging and is thus likely to increase with aging population.

The association between hypertension and higher risk of renal cancer is well described, and in a recent meta-analysis, it was suggested that hypertensive individuals may be at a higher risk of postmenopausal breast cancer, uterine adenocarcinoma and colorectal cancer than nonhypertensive individuals [36]. Chronic renal hypoxia and lipid peroxidation with formation of reactive oxygen species are hypothesized biologic mechanisms underlying the association between hypertension and renal cancer [34, 65].

Higher rates of hypertension are observed after the initiation of certain systemic anticancer treatments traditional (alkylating agents) and newer targeted therapies (Vascular endothelial growth factor signaling pathway (VSP) inhibitors, Bruton's tyrosine kinase inhibitor, proteasome inhibitors and epidermal growth factor receptor tyrosine kinase inhibitors) [66–69] (Table 1).

The probable mechanisms for VSP inhibitor-induced HT are endothelial dysfunction secondary to reduced nitric oxide bioavailability, increased vascular and renal endothelin production, increase in vascular tone, vascular rarefaction and renal thrombotic microangiopathy with secondary glomerular structural and functional changes that lead to proteinuria and hypertension [70–72]. Alkylating agents can cause HT due to endothelial dysfunction and arterial vasoconstriction [73]. Steroid-induced hypertension is likely due increased patient's sensitivity to vasoactive substances and salt and fluid retention [74]. In patients with head and neck cancer, surgery or radiation therapy that involves the head or neck is associated with difficult-to-treat labile hypertension and hypertensive crisis likely due to baroreflex failure [75].

HT is also an important risk factor for chemotherapy-induced cardiotoxicity [76]. In patients who developed HT after receiving VSP pathway inhibitors, HT was associated with better progression free and overall survival [67]. Patients with hypertension should receive guideline directed therapy while taking into consideration the associated comorbidities and potential drug–drug interactions [77]. Optimal management of hypertension will minimize the risk of end-organ damage and allow completion of cancer therapy. The angiogenesis task force of the National Cancer Institute investigational drug steering committee has also issued recommendations for the prevention and management of hypertension in patients receiving angiogenesis inhibitors [78].

4 Diabetes

India has the second highest number of patients with diabetes in the world [79]. Prevalence of DM among newly diagnosed cancer patients is estimated to be 8–18% [80]. The risk of death increases by 40% in patients having DM at the time of cancer diagnosis [81]. High blood sugar levels with or without prior history of diabetes will develop in 32–60% of cancer patients [82–86]. Cancer patients with metabolic disease carry high risk of tumor recurrence, metastasis or fatal outcome than those cancer patients without metabolic disease [87]. Certain systemic anticancer therapies and steroids can cause high blood sugar levels in patient undergoing cancer treatment.

Type 2 DM has been associated with breast, intrahepatic cholangiocarcinoma, colorectal and endometrial cancer, with inconclusive or no evidence for an association with other cancer sites [25]. Risk factors such as aging, obesity, dietary habits, physical inactivity are common to both diabetes and cancer [88]. The interlink between diabetes and cancer is complex with multiple cascades at molecular levels. Hyperinsulinemia, insulin resistance, hyperglycemia, obesity and mediators of chronic inflammation are all markers of carbohydrate metabolism dysfunction which play a major role in mechanisms promoting cancer development and progression in patients with DM [89]. High blood glucose levels have the ability to prevent cancer cells from apoptosis process and thus leading to more aggressive cancer phenotype [90]. The apoptosis-promoting effects of metformin an oral hypoglycemic agent on different cancers by increase of apoptotic genes have been demonstrated [91, 92]. It was observed that pioglitazone increases risk of bladder cancer although this risk was not statistically significant, the increased risk, as previously observed, could not be excluded [93].

L-asparaginase, a cytotoxic chemotherapeutic agent, can induce hyperglycemia through both direct and indirect effects [94]. In patients with baseline impaired glucose tolerance, steroids cause postprandial glucose elevation. However, it is important to note that nondiabetic patients can also develop corticosteroid-induced hyperglycemia [95–97]. This generally reverts back to normal after stopping of steroids; however, it is important to address in order to avoid short-term complications [97], Mammalian target of rapamycin (mTOR) inhibitors may increase total cholesterol, triglyceride and glucose levels [98]. New-onset autoimmune DM has been reported with immune checkpoint inhibitors [99]. Androgen-deprivation therapy (ADT) with luteinizing hormone-releasing hormone [100], chemoradiation [101], platinum-based chemotherapy [102] and 5-fluorouracil-based chemotherapy [103] have also been associated with hyperglycemia.

In a meta-analysis of postoperative mortality across all types of cancer, the risk was increased in patients with pre-existing diabetes (odds ratio 1.51 [1.13–2.02]), compared with nondiabetic patients undergoing operative cancer management [104]. Hyperglycemia during chemotherapy for hematologic and solid tumors is correlated with increased toxicity [105]. Assessment of patients-associated comorbidities and diabetes-related cardiac, renal or neurologic complications should be done, and patients are managed as per existing guidelines. The focus of managing hyperglycemia in patients who are ongoing active cancer treatment should be on avoiding acute and subacute outcomes such as dehydration from polyuria, infection, catabolic weight loss, hyperosmolar nonketotic states and diabetic ketoacidosis [106].

5 Chronic Obstructive Pulmonary Disease (COPD)

The existence of comorbidities in lung cancer can impact not only survival but quality of life as well [107, 108]. WHO reports that 3.0 million lives were lost due to chronic obstructive pulmonary disease in 2016, while 1.7 million died of lung cancer. Data suggests a COPD prevalence of around 50–80% in lung cancer. In a Danish study, COPD was coexistent in 68% of lung cancer patients [109]. Indian data showed a COPD prevalence of 41.9% in lung cancer [110]. The risk of lung cancer in COPD is approximately 167 per 10,000 person-years as compared to the overall risk of 6.1 per 10,000 person-years [111]. The relationship is reciprocal and lung cancer was noted as a leading precursor of death in patients with early COPD [112].

Emphysema was an indicator of poor overall survival independent of tumor staging [113]. Poor lung function and overall poor performance status due to COPD may often be a cause for deferring or delaying a curative lung surgery [114]. In a series of 455 patients with COPD and lung cancer, those with severe COPD had reduced cumulative survival after 2 and 5 years compared to patients with nonsevere COPD. There was a 69% increased risk of mortality in patients who had severe COPD [110]. A meta-analysis of six studies of COPD and postresectional lung cancer concluded that COPD was associated with lower overall survival, prolonged mechanical ventilation and higher rates of pneumonia [115]. Other potential contributory factors that worsen cancer quality of life as well as affect overall survival are systemic cachexia and sarcopenia. These are often found in both COPD and lung cancer due to the effects of pro-inflammatory cytokines such TNF α IL-6. It also leads to poor tolerance to therapy, poorer functional status and decreased quality of life [116].

In the light of the above associations, the detection of COPD in lung cancer patients and its optimal management is an essential component to improve lung cancer survival and surgical outcomes. In a Danish study, among lung cancer patients, only 31% of COPD patients had been diagnosed and only 33% had received guideline appropriate treatment prior to enrolment in the study [109]. COPD management is a multipronged approach, and it includes appropriate pharmacotherapy, pulmonary rehabilitation, nutritional rehabilitation and identification and addressing of issues such as depression related to chronic illness. The role of pulmonary rehabilitation in this context is noteworthy. Pulmonary rehabilitation including exercise training that includes both endurance and resistance training improves muscle mass, muscle strength and exercise capacity. Also, pulmonary prerehabilitation ahead of lung cancer surgery improves lung function recovery and may reduce postoperative complications such as pneumonia, prolonged air leak, respiratory failure and empyema [117]. Pulmonary rehabilitation in COPD is recommended at a minimum of 2 sessions a week for 6 weeks. However, in the context of cancer patients waiting for surgery, it may not be possible to postpone surgery for this long, the main concerns being disease progression and patient and care taker anxiety. Shorter programs up to 4 weeks have also shown promise, but studies saw poor recruitment due to patient reluctance to wait for so long [118]. Pharmacotherapy for COPD is as per the GOLD guidelines and includes use of bronchodilators, including beta 2 agonists and anticholinergics and inhaled steroids in severe COPD patients with frequent exacerbations. Optimization for COPD is essential even for improving preoperative or prechemoradiation lung functions in this section of patients who already have compromised functions at baseline.

Ferguson reported that a respiratory physician consultation in the early course of assessment increased the probability of lung cancer patients being treated with surgery, radiotherapy, or chemotherapy [119]. Patients with a prior pulmonologist consultation had higher survival rates with estimated survival rates of 24.4% versus 11.1% for 1-year and 8.1% versus 3.7% for 3-year survival. Janaki et al. noted that surgical rates were significantly lower in patients who did not receive a pulmonologist involvement than in those who had a pulmonologist consult. This study also indicated that among patients with early COPD, there was a 20% reduction in mortality risk (HR 0.80 95% CI 0.75–0.85) if they were under treatment by a pulmonologist [120]. Pharmacotherapy, pulmonary physiotherapy and rehabilitation can improve lung functions, cachexia and exercise capacity along with a significant role in reduction of postoperative morbidity and most importantly overall survival, thus emphasizing on a multidisciplinary management of all cancer patients with COPD with a multipronged approach.

6 Interstitial Lung Disease (ILD)

Smokers are at risk of developing ILD as well as lung cancer. Patients with Idiopathic pulmonary fibrosis (IPF) have a relative risk of 7–14 of developing lung cancer as compared to the general population [121–124]. Two to 4% of collagen vascular disease-associated interstitial pneumonia (CVD-IP) patients may develop lung cancer [125, 126]. In various studies [127–130] the incidence of ILD ranges from 2.2 to 3.9% in patients with NSCLC. The prevalence of lung cancer at time of initial diagnosis of ILD has been reported as 6, 17 and 15% [131–133].

Preexisting ILD (PE-ILD) is a risk factor for drug-induced ILD as well as for acute exacerbation of ILD on cancer therapy and impacts subsequent therapy, outcome and quality of life. Presence of PE-ILD is indicative of a poor prognosis for surgical outcomes in lung cancer patients with higher risk of ARDS and acute exacerbation of ILD (AE-ILD) [134–139]. Postoperative complications leading to mechanical ventilation and death were more likely to develop in ILD patients than non-ILD patients [127, 129, 130]. In a review of 50 patients with ILD and lung cancer who were operated, 24% developed an acute exacerbation within 30 days of resection with a high mortality [140]. Fujimoto reported a mortality rate of 36% due to interstitial pneumonitis in lung cancer patients on cancer therapy. Development of pneumonitis was independently associated with pre-existing ILD. Pneumonitis was an independent predictor of overall survival (OS). Performance status worsened after the pneumonitis improved in 62% of survivors and 54% of survivors received no further systemic anticancer therapy once they developed pneumonitis [141].

Asai et al. in their study of 46 patients with pre-existing ILD and lung cancer, observed that chemotherapy-induced AE-ILD developed in 32.6%. They also noted that this AE-ILD was more likely to develop in a usual interstitial pneumonia (UIP) pattern or possible UIP pattern of ILD than in a pattern inconsistent with UIP (80% vs. 9.7%). A UIP or possible UIP pattern of ILD was an independent risk factor for chemotherapy-induced AE-ILD on multivariate analysis [142]. Yano reported an incidence of AEILD of 30.6% in their series of 86 patients with pre-existing ILD and lung cancer [143]. Togashi reported that preexisting ILD is an independent prognostic factor for poorer survival in their series of small cell lung cancer [144]. Johkoh reported that drug-induced was more likely to develop in patients with pre-existing ILD and especially if the remaining normal lung is less than 50%. The risk of developing fatal drug-induced ILD was high if the amount of normal lung tissue remaining was less than 50% [142].

The risk for developing radiation pneumonitis (RP) following conventional and stereotactic body radiation therapy (SBRT) is higher in patients with preexisting ILD [145–149].

In Ueki's study, the incidence of ≥Grade 2 RP was 55.0% and that of ≥Grade 3 RP was 10.0% in patients with preexisting ILD. Preexisting ILD was an unfavorable prognostic factor for NSCLC patients treated with either chemotherapy or surgery [128, 138, 139, 150].

ILD also adversely affects survival [129]. The 5-year survival rates in pathologic stage IA lung cancer patients with idiopathic pulmonary fibrosis (IPF) were 54.2% and in those without IPF were 88.3% in Saito's study [151].

7 Tuberculosis

Tuberculosis (TB) and cancer are public health problems contributing to mortality of 1.7 million and 8.8 million deaths, respectively, globally. Seven countries accounted for 64% of the 10.4 million cases of TB in 2016, with India leading the count [152–154] Simonsen et al. showed that the risk of developing TB was highest 3 months preceding and immediately postcancer diagnosis, perhaps due to lowered immunity due to the cancer. This risk remained elevated beyond 5 years of follow-up with HR of 2.48 (95% confidence interval [CI]: 1.99–3.10) [154]. A retrospective analysis from China, of data from a self-reported questionnaire, reported that patients with tuberculosis had an eightfold higher (25 vs. 3.1 per 1000 person-years) risk of lung cancer mortality than those without [155]. Tobacco use while contributing to 22% cancer deaths also increases risk for tubercular disease and death.

In a meta-analysis, adult patients with cancer had an incidence rate ratio (IRR) of TB of 2.61 (95% CI 2.12–3.22).The IRR was 3.53 (95% CI 1.63–7.64) in hematological malignancies (HM), and in solid cancers in adults, it was 2.25 (95% CI 1.96–2.58) with head and neck cancers and then lung cancers leading the count [156]. Similar findings have been noted in our center as well. This is due to altered Th1 response due to HM itself as well as chemotherapy, monoclonal antibodies and immunosuppressive condition of hematopoietic stem cell transplantations. Additionally, cancers of the aerodigestive tract cause weakening of the local barriers predisposing to TB [157]. Fujita et al. identified that old radiologic changes were seen at initial evaluation and before initiation of cancer treatment more commonly in cancer patients who developed TB. They also noted that chest radiograph with fibro-nodular disease, was a risk factor for the development of active TB emphasizing the need for x ray chest prior to initiation of cancer treatment [158]. Relying only on Pet imaging to diagnose metastatic disease without histopathological confirmation in high TB burden countries may inadvertently upstage the malignancy as TB can mimic cancer in PET [159, 160]. While treatment of tuberculosis is as per national guidelines, oncologists need to bear in mind the Cytochrome CYP3A4 induction by Rifampicin (R) reducing the serum levels of drugs like erlotinib, gefitinib, imatinib, dasatinib, etc. which are metabolized hepatically, primarily by CYP3A4. Tuberculosis delays the initiation of cancer treatment. Anticancer therapy is usually started 2 weeks after initiation of antitubercular therapy when infectivity is considered to be decreased. However, since this may result in treatment delay, it could result in cancer progression, which could negatively affect the prognosis.

8 Latent TB Infection (LTBI)

Approximately one-fourth of the world has latent TB (have been infected by TB bacilli but have not developed disease) with a 5–15% lifetime risk of developing disease. Though WHO recommends either a tuberculin skin test (TST) or interferon-gamma release assay (IGRA) to test for LTBI, a combined approach with tuberculin skin test and different interferon-γ release assays might be the best option (after ruling out active disease). This is due to the lower sensitivity of IGRA in resource-poor settings contributed by low immunity of patients (either due to advanced disease, HIV or malnutrition), blood collection errors, or poor assays [161, 162]. Most TB guidelines do not address the risk factors for developing active TB in the cancer patient population nor do they address the possibility of latent tuberculosis infection (LTBI) in cancer patients or discuss the need for LTBI treatment in these immunocompromised patients. WHO guidelines recommend testing and treatment for LTBI in patients who are preparing for an organ or hematological transplant, receiving dialysis, being started on anti-TNF treatment and silicosis, because of the high risk of LTBI progressing to active TB disease in these patients. WHO recommends Isoniazid (H) monotherapy for 6 months/3 month daily or weekly H and R for LTBI treatment in both adults and children in countries with high and low TB incidence [163]. Notably, besides the above mentioned factors, hematologic malignancies, immunosuppression and head and neck cancers have been identified by US and Canadian guidelines as important risk factors for developing active tuberculosis and recommend screening for LTBI [164–166]. Presently, there are no established local guidelines and policies for screening and treatment of LTBI in cancer patients in high TB burden countries like India.

1 Principles of Genetics in Oncology

The genetics of cancer encompasses its hereditary aspects and germline mutations as well as the genetic mechanisms underlying cancer development through somatic mutations. Hanahan and Weinberg in the year 2000 described six hallmarks of cancer-sustaining proliferative signaling, resisting cell death, enabling replicative immortality, evading growth suppressors, inducing angiogenesis and activating invasion and metastasis. They subsequently added two hallmarks—reprogramming of energy metabolism and evading immune destruction along with two enabling characteristics—tumor promoting inflammation and genomic instability and mutation [1]. Genomic instability and mutations play a central role in the complex process of cancer development, cancer metastases and resistance to therapy.

Until the 1960s, cancer genetic studies were confined to syndrome description, patterns of inheritance and cytogenetic abnormalities of hematological and pediatric cancers. A series of ground-breaking discoveries in the 1970s and early 1980s, all awarded with the Nobel Prize, radically changed our understanding of cancer biology and genetics. These included discoveries of oncogenes causing cellular transformation by Harold Varmus and Michael Bishop [2] at the University of California, San Francisco (UCSF); the recombinant DNA technology by Paul Berg and other scientists at the Stanford University and UCSF; Sanger sequencing by Frederick Sanger in Cambridge; and the polymerase chain reaction (PCR) by Kary Mullis in California. The Human Genome Project, launched in 1990 by the US National Institute of Health (NIH) and Department of Energy and joined by the UK Wellcome Trust Sanger Institute and other centers in Germany, France, China and Japan, reported the "draft human genome" in the year 2000 and the "complete human genome" in the year 2003 [3]. Unprecedented developments allowed continued reduction in time and cost of genome sequencing, making it one of the very few large-scale technologies to defy Moore's law of doubling of "compute power" every 2 years [4]. This set the stage for large scale cancer genome projects like The Cancer Genome Atlas (TCGA) of the United States and the International Cancer Genome Consortium (ICGC), in which India is one of the founding members [5]. These studies established the genomic landscape of diverse cancers and identified key genes and mutations that could be used in precision medicine and can-

cer risk assessment. Of the 22,000 protein coding genes and even higher number of genes that code for long intervening non coding RNA (lncRNA) and MicroRNAs [6], several hundred are now implicated in cancer development and progression.

2 Germline and Somatic Variants

Inherited or **germline** genetic variants are present in every cell of the body, including the tumor cells and are studied for evaluating inherited monogenic or polygenic cancer risk or for their pharmacogenomic relevance. The acquired or **somatic** genetic alterations are present only in the cancer cells and are studied to understand genetic mechanisms of cancer and improve diagnostic, prognostic and treatment methods of cancer. Germline variants are present in nearly 50% or 100% sequencing reads in their heterozygous or homozygous states, respectively. However, the allele frequency of somatic variants is highly variable, making it difficult to ascertain their zygosity. This is due to varying admixture of normal and tumor cells in a biopsy sample, variation in the number of clones or subclones of tumor harboring a somatic variant and issues in variant calling through stringent bioinformatics pipelines. Ideally, a variant identified in a tumor sample can be called a true somatic variant only after excluding its germline origin by sequencing normal tissue or blood derived DNA. In absence of this information, any variant identified in a tumor sample with an allele frequency approaching 50% or 100% raises the possibility of this variant being of germline origin and the hereditary implications. Compared to germline variants, confident identification of a somatic variant and its classification is more difficult. This is due to technical issues in sequencing the degraded DNA extracted from old tumor blocs, artifacts, tumor heterogeneity and abundance of uncharacterized passenger somatic variants. For somatic variants, there are specialized and curated databases and guidelines for interpretation and classification but a consensus remains elusive [7].

3 Oncogenes and Tumor Suppressor Genes

Broadly, the cancer-associated genes are classified as proto-oncogenes, which become oncogenes after a gain of function (GoF) mutation, or the tumor suppressor genes (TSG), which promote cancer development if they have a loss of function (LoF) mutation. TSGs such as BRCA1, BRCA2, MLH1, MSH2, etc. are important from the perspective of cancer biology, inherited risk and more recently for precision medicine using synthetic lethality and cancer immunotherapy. Oncogenes such as K-RAS, Her2Neu and EGFR govern aggressiveness of certain tumors and used for biomarkers, molecular profiling, companion diagnostics or therapeutic targets. The major difference between oncogenes and TSGs are shown in Table 1. Mutations in the TSG could either be inherited or acquired but mutations in oncogenes are almost always acquired, with the exceptions being the RET and MET oncogene. The increasing clinical and research-based exome or genome sequencing often identifies structural or

Table 1 Role of oncogenes and tumor suppressor genes

	Oncogenes	Tumor suppressor genes
Examples	Her2Neu, K-RAS, MYC, EGFR, RET, MET, BRAF, etc.	BRCA1, BRCA2, MLH1, MSH2, MSH6, TP53, APC, PALB2, STK11, RB, VHL, TSC, etc.
Major cellular role	Cell signaling that drives cell division or proliferation under specific physiological and pathological conditions	Controls integrity and efficiency of DNA repair, cell division, apoptosis and other housekeeping and homeostasis functions during embryogenesis, growth, differentiation and senescence
How mutations perturb cellular behavior, contribute to hallmarks of cancer	Instead of context dependent and reversible activation, they become constitutively activated due to specific point mutation or overexpression. This promotes sustained proliferation, uncontrolled growth and aggressive cellular phenotype	Instead of maintaining homeostasis, mutations in TSGs cause impaired and inefficient repair of specific types of DNA damage, impaired cell cycle control, apoptosis and reprogramming of energy metabolism
Nature of cancer-causing mutations	Gain-in-Function: Gene amplification with increase in the copy number or a heterozygous missense point mutation at a specific codon results in Gain-in-Function of uncontrolled and sustained multiplication. Usually, it is an acquired somatic mutation but rarely it is an inherited germline mutation (e.g., RET)	Loss-of-Function: Truncating mutations (nonsense or frameshift indels); absence of protein (chromosomal deletion) or an aberrant nonfunctional protein (splice site or certain pathogenic missense mutations). For total loss of a specific tumor suppressor activity, both alleles are inactivated as per Knudson's hypothesis
Role in cancer prevention and precision oncology	Specific mutations and activated oncogenic signaling in tumor used for molecular classification with prognostic and predictive value. Specific driver mutations or amplifications in kinases and other genes can be blocked by small molecule inhibitors (e.g., imatinib) or monoclonal antibodies (e.g., trastuzumab)	Identification of germline pathogenic mutation is used for hereditary cancer risk, extended family testing and cancer prevention. Germline or somatic mutation in DNA damage repair pathways genes predict platinum sensitivity and used in synthetic lethality approach (PARP inhibitors). Germline MMR gene mutations predict response to immunotherapy

functionally relevant genetic alterations in genes that are yet to be classified as oncogenes or TSGs. Genes that harbor protein truncating or splice site mutations in several tumors, are expected to be tumor suppressors, especially if such mutations are seen with loss of heterozygosity (LOH) events in the tumor. In contrast, genes with missense mutations in particular codons or genes showing amplification in several tumors, are likely to be oncogenes. Some genes such as NOTCH1 show a tissue and cellular context dependent role as an oncogene or as a tumor suppressor gene [8]. The TCGA and ICGC consortium projects through whole exome, genome and transcriptome analysis of a large number of diverse human cancers have established the genomic landscape of various human cancers and the mutational signatures of different carcinogenic exposures. These and other studies discovered new driver genes, previously unknown genetic mechanisms such as chromothripsis, and revealed that cancer genomes have four or five driver mutations in the coding and noncoding genomic elements and germline variants also influence the patterns of somatic mutation and tumor evolution [9].

4 Classification and Reporting of Genetic Variants

The sequence in which the four nucleotides, adenine, thymine, guanine and cytosine, are arranged in the genomic DNA is distinct for each life form and unique for every individual within a species. Any nucleotide base in an individual that differs from the reference healthy population genome is a genetic variant. The full spectrum of human genetic diversity is yet to be documented in several non-Caucasian races. Of the hundreds to thousands of genetic variants in each individual, overwhelming majority are polymorphic variants of little or no biological consequence or disease risk. However, some variants that are rare in the population may confer disease susceptibility in individuals with these rare variants. The nucleotide sequence of the region of interest is determined using an appropriate DNA sequencing technology, mapped to the reference sequence derived from normal healthy population and seen whether it is an exact match or has one or more variants. The standardized nomenclature and reporting for DNA and amino acid sequence variants developed by the Human Genome Variation Society (HGVS) helps to develop common genome databases for reproducible genetic analysis and standardized reporting, with minimum risk of false variant interpretation [10]. Variants are classified and interpreted in terms of their effect on the expression of the gene or the structure and function of the protein they code. HGVS recommends DNA genetic variants to be classified as **substitutions** of one nucleotide base with another, **insertion**, **deletion** or insertions with deletions of one or more bases, **duplications**, **inversions**, **repeated sequences** or **complex** variants. The genetic alterations identified in cancer associated genes and their disease risk is described in Table 2.

Genetic alterations are described to indicate their location (chromosome, gene, exon or intron); zygosity (heterozygous or homozygous) and nature (substitution, indel, etc.) using the HGVS nomenclature. Using the prefix “c.” for the coding DNA position and prefix “p.” for the amino acid position, the variant allele is described with its known or predicted effect. Technically, any genetic variant is a mutation but the term mutation has a connotation for disease risk. To avoid misinterpretation, all alterations should be called ‘variants’ along with a description of their likely pathogenicity, and not as ‘mutations’. The five-tier variant classification system proposed by the International Association for Research in Cancer (IARC) [11] and adapted by the American College of Medical Genetics and Genomics and the Association for Molecular Pathology (ACMG/AMP), recommends that all variants should be described as either (1) benign; (2) likely benign; (3) uncertain significance; (4) likely pathogenic; or (5) pathogenic [12]. It is based on evidence from population, computational and functional data available in freely accessible disease and population databases like dbSNP, HGVS, 1000 Genome, gnomAD, Leiden Open Variation Database (LOVD) and ClinVar which archives reported human variants with disease associations and supporting evidence [13]. The ACMG, AMP and the International Society for Gastrointestinal Hereditary Tumors (InSiGHT) [14] use the following five classes of genetic variants:

Pathogenic (class 5) or likely pathogenic (class 4) variants: These variants significantly alter the gene and coded protein and are known or predicted to cause cancer. With the rare exception of Ashkenazi Jews and some inbred populations with a 1–2% population frequency of class 5 founder mutations, pathogenic germline variants are very rare in normal population. The converse is not true and every rare allele with population frequency of <1% or < 0.1% may not be pathogenic.

Variant of uncertain clinical significance VUS (class 3): A missense or inframe indel variant is considered as VUS if it is rare or absent in the reference normal population and comprehensive studies to evaluate its pathogenicity are either not available or inconclusive. Due to major differences in the genetic constitution between different races and communities, a missense alteration which may be a polymorphic variant in a less studied population, may be very rare or absent in another population used as reference. Thus, a polymorphic benign MLH1 gene variant present in 4% healthy individuals from a particular Indian community, may be very rare or absent in the wider Indian or Caucasian reference genome. In absence of this knowledge, it will be reported as a VUS.

Benign (class 1) or likely benign (class 2): These are deep intronic, synonymous or missense polymorphic variants, often present in >1% of healthy individuals.

Table 2 Type of genetic alterations and their effect

Genetic alteration	Effect on coded protein or gene expression	Biological role in cancer	
		Germline variants	Somatic variants
Base substitution in deep intronic or intergenic	No effect. Rarely, it may introduce a cryptic splice site or alter gene expression	SNPs with no or very mild modulatory effect in some cancers Very rarely pathogenic	No effect
Base substitution in 5′ or 3′ UTR	Usually no effect Sometimes may alter UTR regulatory elements	SNPs with no or very mild modulatory effect in some cancers. Rarely pathogenic[a]	No effect
Base substitution in coding exonic region	Codes same AA (synonymous or silent)	SNPs with no or very mild modulatory effect in some cancers. Very rarely pathogenic[a]	No effect
	Codes different AA (missense variant). Protein structure or function may or may not change	SNPs with no or very mild modulatory effect or pharmacogenomic relevance Pathogenic in specific codons of oncogenes RET and MET (GoF) or few TSGs, e.g., TP53 (LoF)	In oncogenes, GoF variants in specific codons are driver and targetable, e.g., BRAFV600E In TSGs, most are passenger but few are LoF pathogenic variants
	Codes for Stop codon (stopgain or Nonsense), causing truncated protein	In TSGs almost always pathogenic	In TSGs usually pathogenic
	Abolishes Stop codon (stoploss) causing exon retention	In TSGs almost always pathogenic	In TSGs usually pathogenic
Base substitution in essential splice site	Aberrant splicing and aberrant protein due to retention/deletion of exon/intron	In TSGs almost always pathogenic	In TSGs usually pathogenic
Small insertion or deletion in exons	In-frame insertion or deletion adds or removes 1 or 2 AA	Usually, polymorphisms with no or mild modulatory effect. Rarely pathogenic[a]	No effect
	Frameshift insertion/deletions introduces stop codon with truncated protein	Almost always pathogenic	In TSGs usually pathogenic
Large genomic rearrangement (LGR)	Deletion/duplication of exons/introns with aberrant protein	Almost always pathogenic	In TSGs usually pathogenic
Chromosomal abnormalities or structural variants	Deletions, duplications or translocation of chromosomes cause gain or loss of function of genes or oncogenic fusion products	These are rare in germline and cause congenital syndromes, some with increased cancer risk	Common driver mutations in hematological malignancies and some solid tumors or cause the second hit in TSGs by LOH

UTR untranslated region, *LOH* loss of heterozygosity

[a] Type of mutations which are rarely pathogenic, should be interpreted as likely pathogenic based on multiple lines of evidence, including family studies and functional studies

5 Hereditary Cancer Syndromes

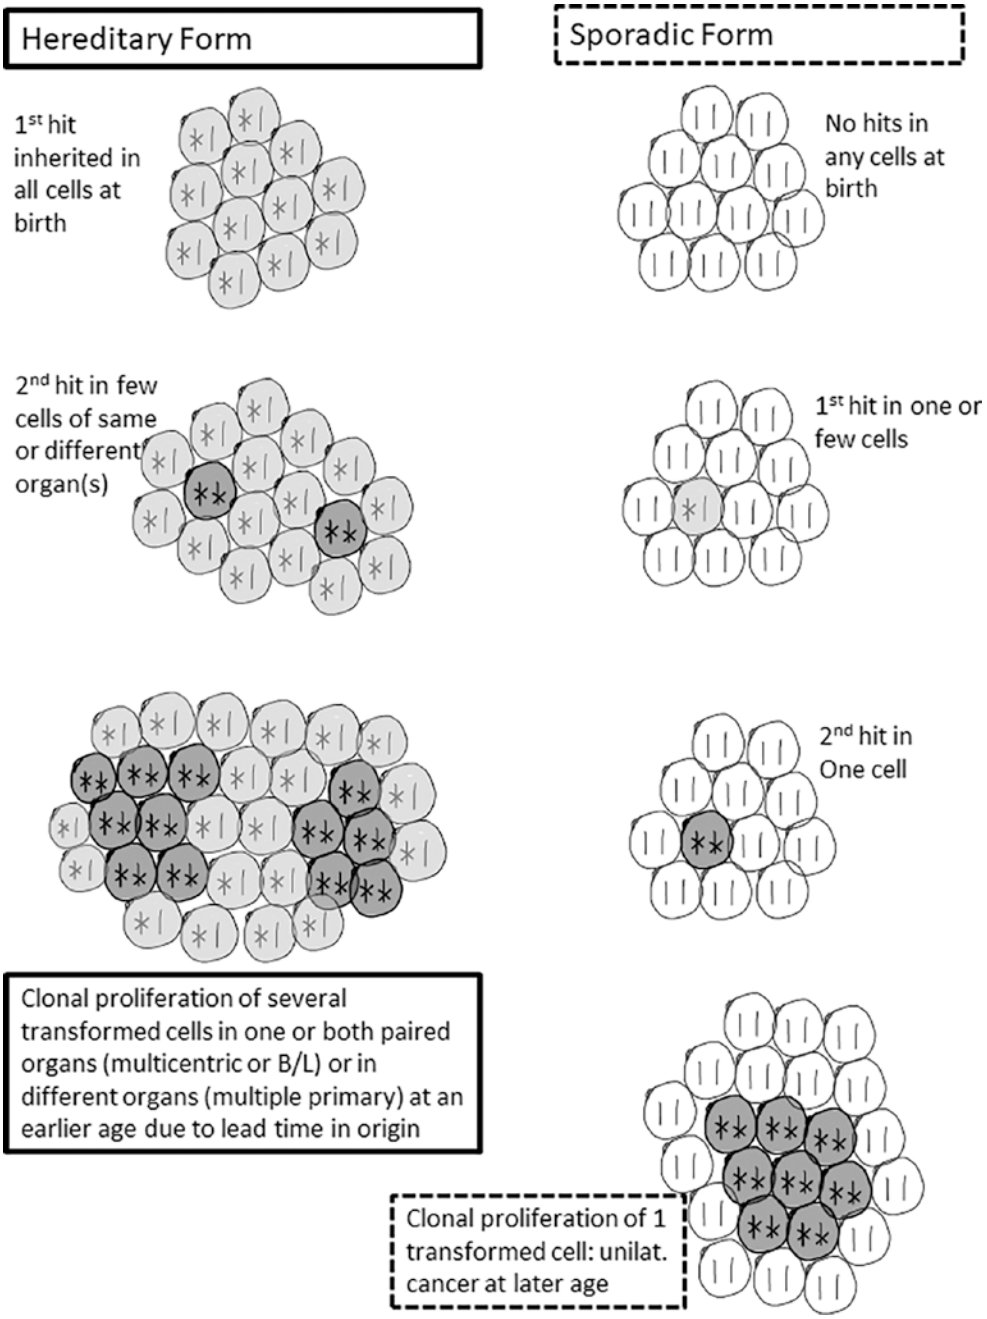
Germline pathogenic or likely pathogenic mutation in cancer susceptibility genes results in a high lifetime risk of developing certain cancers. Over 30 well characterized hereditary cancer syndromes and their variants are known. Barring a few Mendelian recessive syndromes such as xeroderma pigmentosum (XP), constitutional mismatch repair deficiency (CMMRD), MYH-associated polyposis or Fanconi's anemia, all others have a Mendelian dominant pattern of inheritance with a 50:50 chance of passing on the gene mutation and cancer risk to the offspring. While few phenotypic manifestations are unique to a particular gene or syndrome, e.g., carpet of adenomatous polyps in APC mutation or MEN2B phenotype in RET gene mutation, most benign and malignant manifestations are shared between different syndromes and genes. With wider use of genetic testing, it has been established that classical syndromic features of HBOC or Lynch syndrome are uncommon in carriers of BRCA or MMR gene mutation and their families. This is explained by incomplete penetrance, incomplete or unreliable family history and heterogeneity in clinical manifestations. The genetic counseling and testing advice is therefore based on the differential diagnosis of possible hereditary cancer syndromes.

5.1 Universal Features of Hereditary Cancers and the Knudson's Two-Hit Hypothesis

The hereditary form of retinoblastoma (RB) and its bilateral presentation was known long before the underlying genetic mechanism was known. Alfred Knudson in a seminal 1971 paper titled "Mutation and Cancer: Statistical

Study of Retinoblastoma" proposed that two genetic hits are required for retinoblastoma development. Using a semilogarithmic plot of fraction of bilateral and unilateral cases not yet diagnosed with RB against age in months, he derived that the straight line of hereditary RB and curved line of sporadic RB could only be explained by two genetic hits or mutation required for the development of RB. In hereditary RB, all retinal cells must have the first hit at birth and subsequently may have acquired the second hit in one or more retinal cells of one or both eyes. In the sporadic or nonhereditary RB, two successive genetic hits or mutation were acquired after birth in one of the retinal cell. Clonal proliferation of a transformed retinal cell with two hits of the responsible gene (RB1) resulted in the development of the retinoblastoma tumor. This was a major advancement in our understanding of the effect of germline and somatic mutations in one or both alleles of the same gene and later shown as the key feature of how tumor suppressor genes cause cancer with the second copy of the TSG lost through deletion or other mechanisms and causing LOH. The relevance of this genetic model (Fig. 1) of a person born with the first genetic hit (heterozygous germline mutation) and subsequently acquiring the second hit (somatic mutation) later in life explains three key universal features of hereditary cancers.

- High lifetime cancer risk in those born with the one mutated allele (germline first hit).



Hereditary Form
1st hit inherited in all cells at birth
2nd hit in few cells of same or different organ(s)
Clonal proliferation of several transformed cells in one or both paired organs (multicentric or B/L) or in different organs (multiple primary) at an earlier age due to lead time in origin
Sporadic Form
No hits in any cells at birth
1st hit in one or few cells
2nd hit in One cell
Clonal proliferation of 1 transformed cell: unilat. cancer at later age

Fig. 1 Knudson's two-hit model and clinical features of hereditary cancer

- Earlier age at diagnosis in hereditary cancers as compared to their sporadic counterparts.
- Significantly higher incidence of bilateral, multiple primary or multifocal cancers.

5.2 Specific Features of Hereditary Cancer Syndromes

Each hereditary cancer syndrome is defined based on the combination of characteristic features in terms of mode of inheritance, specific cancer types, histological features, age at cancer diagnosis and certain cutaneous, ocular, endoscopic or radiological features. While germline mutation is present in every cell, tissue differences in gene expression and the function of that gene may increase cancer risk in few but not all organs and explain the syndromic manifestations. Dermatological, facial, ocular, endoscopic or imaging findings indicative of an underlying gene mutation are present only in a few syndromes (Table 3). For majority of the common cancer predisposition syndromes, the only clue is a significant family history or personal history of early onset or bilateral cancer, sometimes with specific tumor or molecular characteristics. Some cancers with specific histological features (Table 4) or certain phenotypic features (Table 3) are highly suggestive of a particular syndrome with a specific genetic basis. This should alert the pathologist and clinician to look for other features of that syndrome and consider appropriate genetic evaluation and germline testing.

It is important to note that cancers in some organs like breast, kidney, stomach, pancreas or brain can occur in many hereditary cancer syndromes, sometimes with syndrome specific differences in molecular or histological subtype. Breast cancer is a prominent feature not only of the HBOC syndrome but also of LFS, PJS, Cowden and HDGC syndrome and a less prominent but increasingly recognized feature of Lynch and NF1 syndromes. Knowledge regarding age at breast cancer diagnosis and its receptor status or other cancers and phenotypic features in different hereditary cancer syndromes as shown in Table 5 could guide appropriate genetic testing and risk management.

Autosomal recessive inheritance is very rare and due to homozygous or bi-allelic mutation usually inherited from consanguineous parents or from inbred community. These syndromes include:

Ataxia Telangiectasia (*ATM gene):* Presents with conjunctival telangiectasia, ataxia, immunosuppression and extreme radiosensitivity with 25% risk of hematolymphoid malignancy [17].

Fanconi Anemia (BRCA2 or 21 other FANC family genes): All are autosomal recessive except the X linked FANCB and the autosomal dominant FANCR. It is commonly associated with congenital anomalies and 70 cases have bone marrow failure, 50% have myelodysplastic syndrome, 5% develop acute leukemia and 20% develop head neck, female genital or and anal squamous carcinomas [49].

Constitutive Mismatch Repair Deficiency (CMMRD) Syndrome (MMR genes, most commonly PMS2): Café-au-lait spots with very high risk of CNS, GI and acute leukemias [50].

MUTYH-Associated Polyposis (MAP) Syndrome (MYH gene): Adenomatous with or without serrated or hyperplastic colorectal polyps which are not as profuse as in FAP and have 80% colorectal cancer risk [15, 16, 51].

Xeroderma Pigmentosum (8 genes, XP-A to XP-G and XP-V): Presents with extremely sun-sensitive dry pigmented atrophic skin and lentigines, >90% cases develop squamous or basal cell carcinoma or melanoma over the sun exposed skin, eyelids, conjunctiva or sometimes over the tip of the tongue. Cognitive impairment is seen in 25% cases [52].

Bloom Syndrome (BLM gene coding for RecQ helicase): Presents with skin erythema, telangiectasia, short stature, endocrine and immune deficiency and 80% risk of hematolymphoid, GI, head neck or other malignancy by age 40 years [53].

Autosomal-dominant inheritance due to heterozygous mutation include all common and some rare hereditary cancer syndromes such as HBOC, Lynch, MEN, LFS, RB, PJS, NF1, etc. listed in Table 3.

Age at cancer diagnosis varies in different syndromes, as shown for breast cancer in Table 5. Even for the same gene, the age at diagnosis could vary for different cancers. For example, in BRCA2 mutation carriers, the risk for female breast cancer starts in the early twenties, while the risk for ovarian and prostate cancer starts in the late 30s and 40s, respectively. This information is used in deciding the age at which genetic testing should be done and cancer screening should be initiated and counseling about prenatal or preimplantation genetic diagnosis. Syndromes can be broadly classified as

- **Predominantly childhood cancer predisposition syndromes:** Hereditary retinoblastoma, Wilm's tumor/WAGR syndrome, Fanconi anemia, CMMRD, juvenile polyposis syndrome.
- **Childhood and adult-onset cancer predisposition:** Li–Fraumeni syndrome, MEN2 syndrome, NF1, tuberous sclerosis, XP.
- **Predominantly adult-onset cancer predisposition syndromes:** HBOC, Lynch, FAP, Cowden, Peutz–Jeghers, HDGC, hereditary renal cancers, etc.

Sex differences in cancer predisposition is common in HBOC associated BRCA1, BRCA2, CHEK2, RAD51 and PALB2 genes with the breast or ovary cancer risk being much higher in women as compared to breast or prostate cancer risk in men. The only gene with predominantly male cancer predisposition is HOXB3 with ~35% prostate cancer risk. For MMR, NF1, NF2, APC, RET, RB and few other genes, no major sex differences in cancer risk are observed.

Table 3 Syndromic features and cumulative lifetime risk for specific cancers in mutation carriers (rounded off to nearest 5%/10%)

GENE (Syndrome)	Syndromic phenotypic feature or any benign tumors	Breast	Colorectal	CNS	Endometrial	Gastric	Kidney/Ureter	Ovary	Pancreas	Prostate	Skin	Thyroid	
APC[d] [15, 16] (FAP, Turcot–Gardner)	Extensive adenomatous polyps, osteoma, CHRPE desmoid fibromatosis		95%	5% Medullo		10%				[e]		15% PTC	5% HPB, periampullary or duodenal
ATM[d] [17]	Not in heterozygotes	30%								[e]			Lung[e]
BLM [18]	None	40%											
BMPR1A [19] (Juvenile polyposis synd)	Juvenile hamartomatous or adenomatous polyps in GI (5–100)		40%			[e]							Small bowel[e]
BRCA1[a] [20–23] (HBOC synd)	None	70%						45%	[e]	[e]			Breast cancers usually TNBC
BRCA2[a,d] [20–23] (HBOC synd)	None	70%						30%	10%	15%			Breast cancers usually ER +ve
BRIP1[a] [18, 24]	None	15%						5%					
CDH1 [25] (HDGC synd)	Orofacial cleft	45%				40%							Invasive lobular ca
CHEK2[a] [22, 26]	None	25%								[e]			
FH [27] (HLRCC)	Uterine and cutaneous leiomyoma						RCC-O RCC-Ch						
FLCN [27] (Birt–Hogg–Dubé synd)	Skin fibrofolliculomas, angiofibroma, lung cysts, pneumothorax						RCC-HOCT RCC-P Oncocytoma						
HOXB13 [28]	None									35%			
MEN1 [29] (MEN1 synd)	Pituitary or parathyroid adenoma, NET			40% pituitary		40% NET			70% NET			80% PTh	ACC 40%
MET [27, 30] (HPRC synd)	None						RCC-P1						
MLH1[b] [31] (Lynch synd)	Keratoacanthoma	10%	45%	[e]	45%	5%	10%	10%	5%	15%	5%		HPB 5%
MSH2[b] [31] (Lynch synd)	Keratoacanthoma	15%	45%	5%	60%	[e]	25%	15%	[e]	30%	5%		
MSH6[b] [31] (Lynch synd)	Keratoacanthoma	15%	15%	[e]	45%	[e]	10%	15%	[e]	20%			
NF1[c] [32] (Neurofibroma-tosis type 1)	Neurofibromas, CAL, axillary freckles, Lisch nodule, cognitive defect, plexiform neurofibroma	[e]		25%									MPNST 10%, RMS 5%
NF2[c] [33] (Neurofibromato-sis type 2)	Hearing loss, cataract, Schwannoma, skin lesions, meningioma			95%									Bilat vestibular schwannoma >90%
PALB2[a] [34]	None	35%							[e]	[e]			
PMS2[b, d] [31, 35] (Lynch synd)	None	[e]	15%		15%								

(continued)

Table 3 (continued)

GENE (Syndrome)	Syndromic phenotypic feature or any benign tumors	Breast	Colorectal	CNS	Endometrial	Gastric	Kidney/Ureter	Ovary	Pancreas	Prostate	Skin	Thyroid	
PTEN[c] [36] (Cowden or PTEN hamartoma synd)	FT, COP, PPK, macrocephaly penile freckles, GI hamartomas, LDD/CDG, thyroiditis	70%	20%		20%		10–30% RCC-CC				5%	25%	Lung cancer[e]
RAD50[a] [18]	None	30%											
RAD51-C/D[a] [37]	None	20%						10%					
RB1[d] [38, 39] (hereditary RB)	Dysmorphic features with large deletions in 13q			5% pineal									RB >90%, sarcoma 5%
RET[d] [40] (MEN2A)	Parathyroid hyperplasia											50–100%	PCC 5–25%
RET[d] [40] (MEN2B)	Marfanoid habitus, tongue and lip neurinomas, blubbery lips											100%	PCC 50%
SDHB/C/D [41, 42] (hereditary PGL/PCC)	Paraganglioma						RCC-O RCC-Ch RCC-CC						PGL or PCC 50–60%
SMAD4 [19] (Juvenile polyposis syndrome)	Juvenile hamartomatous or adenomatous polyps, (5–100), HT, connective tissue disorder		40%			[e]							Small bowel[e]
STK11 [43, 44] (Peutz–Jeghers synd)	Lip / oral pigmentation; hamartomatous GI polyps, SCTAT	55%	40%		10%	30%		20%	30%				
TP53 [45] (Li–Fraumeni syndrome)	None	85%	5%	25%			[e]	[e]	[e]	[e]	[e]		Sarcoma 50%, ACC 5%, lung[e]
TSC1/2[c] [46] (tuberous sclerosis)	Facial angiofibromas, shagreen patches. SEN, cortical tubers Lung, eye, heart, renal hamartoma			20% SEGA									
VHL[c] [47] (VHL disease)	Retinal angiomas, renal and pancreatic cysts, NET			80% HB			70% RCC-CC						PCC, inner ear ELST
Rare syndromes (CDKN2A PTCH, WT1) [48]				Medullo (Gorlins)			Wilm's tumor (WAGR)				BCC MM		

ACC adreno-cortical carcinoma, *BCC* basal cell carcinoma, *CHRPE* congenital hypertrophy of retinal pigment epithelium, *COP* cobblestone oral papules, *CAL* café au lait spots, *ELST* endolymphatic sac tumors, *FH* fumarate hydratase, *FT* facial trichilemmoma, *HB* hemangioblastoma, *HBOC* hereditary breast ovarian cancer, *HPRC* hereditary papillary renal carcinoma, *HT* hemorrhagic telangiectasia, *LAM* lymphangioleiomyomatosis, *LDD/CDG* Lhermitte–Duclos disease or cerebellar dysplastic gangliocytoma, *MEN* multiple endocrine neoplasia, *MM* malignant melanoma, *MPNST* malignant peripheral nerve sheath tumor, *NET* neuroendocrine tumors, *PCC* pheochromocytoma, *PPK* palmo-plantar keratosis, *PTh* parathyroid, *PTHS* PTEN hamartoma syndrome, *RB* retinoblastoma, *RCC* renal cell carcinoma, *RCC-CC* clear cell, *RCC-Ch* chromophobe, *RCC-P* papillary, *RCC-O* oncocytic, *RCC-HOCT* hybrid oncocytoma chromophobe tumor, *RMS* rhabdomyosarcoma, *SCTAT* sex cord tumor with annular tubules, *SDH B/C/D* succinate dehydrogenase subunits B, C, D, *SEN* subependymal nodules, *SLE* systemic lupus erythematosus, *VHL* von Hippel–Lindau's disease

[a] BRCA1/2 and its interacting genes

[b] Mismatch repair genes and its interacting genes

[c] Phakomatosis/neurocutaneous syndromes

[d] Genes with major phenotypic or penetrance difference depending on mutation location and zygosity

[e] Risk higher than population risk but not very high risk

Table 4 Cancer types highly suggestive of a syndrome

Cancer type specific to a syndrome/ gene	Syndrome (gene)
Hypodiploid acute lymphoblastic leukemia	Li–Fraumeni syndrome (*TP53*)
Choroid plexus tumor or carcinoma	
Acoustic neuroma (often bilateral)	NF2 syndrome (*NF2*)
Optic pathway glioma	NF1 syndrome (*NF1*)
Malignant peripheral nerve sheath tumor	
Cerebellar or spinal hemangioblastoma	Von Hippel–Lindau's disease (*VHL*)
Subependymal giant cell astrocytoma (SGCA)	Tuberous sclerosis (*TSC1/ TSC2*)
Retinoblastoma—multicentric or bilateral	Hereditary retinoblastoma (*RB1*)
Multiple basal cell carcinoma	Gorlin's syndrome (PTCH1)
Medullary thyroid cancer	MEN type 2 (*RET*)
Diffuse gastric cancer	Hereditary diffuse gastric cancer (*CDH1*)
Renal cancer—Hybrid oncocytoma and chromophobe	Birt–Hogg–Dube syndrome (*FLCN1*)
Renal cancer—Papillary type 1	Hereditary papillary renal cell cancer (*MET*)
Renal cancer—Papillary type 2	Hereditary leiomyomatosis and renal cell cancer (*FH*)
Microsatellite unstable or MSI high colorectal or endometrial carcinoma	Lynch syndrome (heterozygous MMR genes)

Penetrance, cumulative cancer risk and genotype–phenotype correlation are the most important considerations in counseling families. Penetrance refers to the proportion of individuals with phenotypic manifestation of the underlying genotype in terms of cancer development and syndrome specific phenotypic features such as polyps, facial appearance, eye or skin signs (see Table 3). Age and gender specific cumulative risk of a particular cancer in confirmed mutation carriers of a gene is the most useful in clinical practice. Few syndromes such as FAP and MEN2B have a near complete penetrance, both for syndromic phenotypic features and cancer development. The common hereditary cancer syndromes such as HBOC, Lynch, LFS, RB, etc. with high penetrance gene mutations have a cumulative cancer risk of 50–95%. Heterozygous mutations in ATM, BARD1, BLM, BRIP1, CHEK2, HOXB13, NBN, PALB2, PMS2, RAD50, RAD51 and a few others have an intermediate or moderate penetrance with cumulative cancer risk between 20 and 50% (see Table 3). The penetrance and phenotype associated with mutations in certain genes can be greatly affected by the location of the mutation within the genes. Mutations in certain regions of the APC gene cause the attenuated form of FAP or carry significantly higher risk for desmoid tumors [15]. Similarly RET gene mutation at 918 codon (M918T) produce classical MEN2B phenotype and childhood medullary thyroid cancer (MTC), while codon 634 (C634R) produce MEN2A with adult onset MTC in absence of MEN2B phenotypic features [40]. Of the four MMR genes, extracolonic cancers in general and skin cancers in particular

Table 5 Inherited breast cancer risk in different syndromes

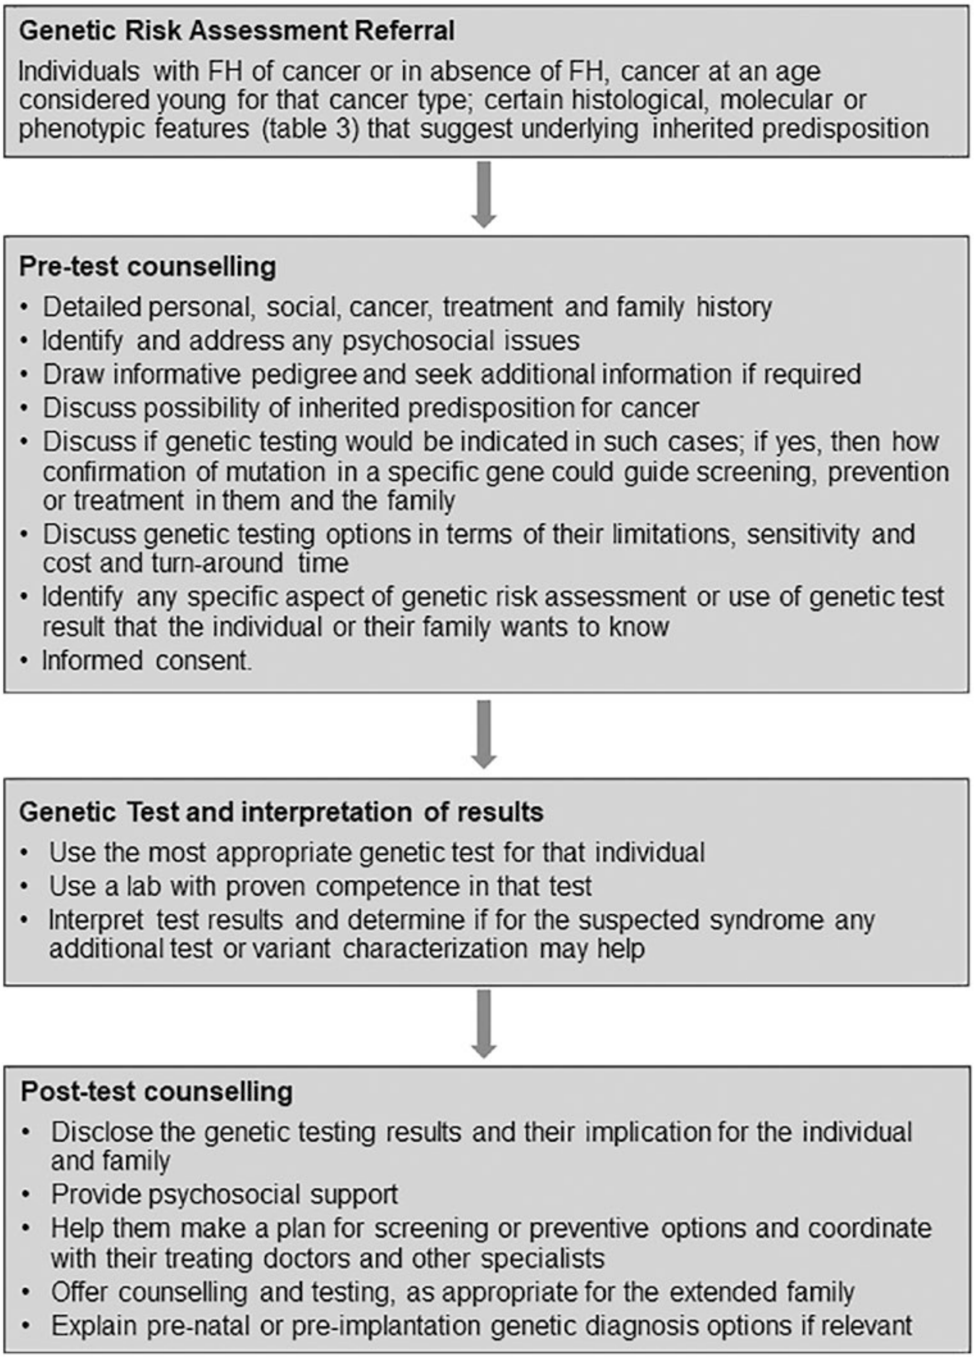
Syndrome (*Gene*) [Ref]	Cancer risk			Age at breast cancer diagnosis	Receptor status	Phenotypic features
	Breast	Ovary	Others			
HBOC (*BRCA1*) [20–23]	+++++	+++	+/–	Early onset	IDC TNBC	No
HBOC (*BRCA2*) [20–23]	++++	++	+ Pancreas, Prostate	Early and late onset	IDC ER+ve Her2−ve	No
HBOC (*ATM, PALB2, RAD51*) [18, 34, 37]	++	+/–		Early and late onset	Not described	No
LFS/LFL (*TP53*) [45]	++++	+	++++	Very early onset	IDC ER+/– Her2+	No
PJS (*STK11*) [43, 44]	++	+	++ GI	Early onset	IDC ER+ve Her2−ve	Pigmentation and polyps (see Table 4)
Cowden (*PTEN*) [36]	++			Early onset	Not described	Cutaneous (see Table 4)
Lynch (*MMR*) [31]	+	+	++++ GI, uterus GU, brain, skin	Early onset	Not described	No
NF1 (*NF1*) [32]	+	–	CNS	Early and late onset	IDC ER+/– Her2+	Cutaneous, skeletal, CNS (see Table 4)
HDGC (*CDH1*) [25]	+++	–	++++ Diffuse gastric cancer	Early onset	Lobular carcinoma	No

GI gastrointestinal, *GU* genitourinary, *IDC* infiltrating duct carcinoma, *CNS* central nervous system, *TNBC* triple negative breast cancer are far commoner in MSH2 as compared to MLH1, MSH6 and PMS2 while the cumulative cancer risk is significantly lower in PMS2 gene mutation.

6 Genetic Risk Assessment and Genetic Counseling

Genetic risk assessment is the process of suspecting and confirming inherited predisposition to cancer through genetic counseling, pedigree analysis and germline genetic testing when indicated. The treating oncologist, pathologist or radiologist refers for genetic risk assessment if based on personal and family history of cancer, or certain histological, radiological or phenotypic features, they suspect inherited cancer predisposition. Inherited cancer risk is confirmed through appropriate germline genetic testing which is preceded by **pretest genetic counseling** and followed by **posttest genetic counseling** (Fig. 2).

Genetic counseling, especially for cases with significant family history or a known mutation, should preferably be imparted through specialized genetics clinics by clinicians or counselors with knowledge and experience in various aspects of hereditary cancers including the utility or limitations of



Genetic Risk Assessment Referral

Individuals with FH of cancer or in absence of FH, cancer at an age considered young for that cancer type; certain histological, molecular or phenotypic features (table 3) that suggest underlying inherited predisposition

Pre-test counselling

- Detailed personal, social, cancer, treatment and family history
- Identify and address any psychosocial issues
- Draw informative pedigree and seek additional information if required
- Discuss possibility of inherited predisposition for cancer
- Discuss if genetic testing would be indicated in such cases; if yes, then how confirmation of mutation in a specific gene could guide screening, prevention or treatment in them and the family
- Discuss genetic testing options in terms of their limitations, sensitivity and cost and turn-around time
- Identify any specific aspect of genetic risk assessment or use of genetic test result that the individual or their family wants to know
- Informed consent.

Genetic Test and interpretation of results

- Use the most appropriate genetic test for that individual
- Use a lab with proven competence in that test
- Interpret test results and determine if for the suspected syndrome any additional test or variant characterization may help

Post-test counselling

- Disclose the genetic testing results and their implication for the individual and family
- Provide psychosocial support
- Help them make a plan for screening or preventive options and coordinate with their treating doctors and other specialists
- Offer counselling and testing, as appropriate for the extended family
- Explain pre-natal or pre-implantation genetic diagnosis options if relevant

Fig. 2 Genetic risk assessment: referral, genetic counseling and genetic testing

various genetic testing and cancer prevention methods and the associated ethical, legal and social issues (ELSI). Families with hereditary cancers face a range of ethical and socio-cultural issues which may be accentuated with genetic testing and should be addressed during genetic counseling. Guilt of passing the cancer risk to children is not uncommon. Outside Europe and North America, most countries do not have mechanisms and specific legislation for protection against genetic discrimination at work place or insurance. Adherence to the principles of genetic counseling helps in minimizing the psycho-social impact of hereditary cancer risk and genetic test results on an individual or a family. These include autonomy, empathy, beneficence, nonmaleficence, nondirectiveness and informed decision making while maintaining confidentiality and privacy. The informed consent or assent should include all these aspects. Some individuals may require referral for specialized psychological counseling.

A detailed and informative pedigree using standard symbols and methods with details of any phenotypic manifestations and cancers in the family is the most important tool in making syndromic differential diagnosis, estimating the likelihood of inherited predisposition and the genetic testing that may be useful. Medical records and details of cancers in the family are often not available in developing countries and verbal autopsy techniques are heavily relied upon to ascertain the most probable cause of death or type of cancers in the family. For example, ovarian cancer which is the syndrome defining cancer in HBOC is frequently misreported as "abdominal," "stomach," or "uterus" cancer by the relatives. History of recurrent ascites or bloated abdomen with or without cachexia in the last stages of a woman known to have died of cancer is suggestive of terminal ovarian cancer.

7 Germline Genetic Testing

Traditionally, genetic testing was recommended if there was a strong family history or the probability of germline mutation was predicted to be >10% by online tools such as BOADICEA (http://ccge.medschl.cam.ac.uk/boadicea/), BRCAPro or MMRPro (http://astor.som.jhmi.edu/BayesMendel/). This threshold is not strictly applied now with increasing identification of mutations in individuals who do not fit the traditional genetic testing criteria; germline genetic testing being done to identify individuals who may benefit with precision medicine approaches; and the wider availability of germline genetic testing. Genetic testing options are provided to individuals with a reasonable prospect of harboring germline mutation in a moderate to high penetrance gene. In patients with recurrent or refractory breast, ovary, prostate, pancreatic, GI or GU cancers, germline genetic testing is being increasingly done to identify germline mutation in BRCA1, BRCA2 or other DNA damage repair pathway genes to predict sensitivity to platinum agents or PARP inhibitors or in the MMR pathway genes that predict benefit with immunotherapy.

During genetic counseling, individuals are helped to make an informed decision and provide consent based on the availability and access to a genetic test, its cost, turnaround time and need for additional testing if the test results are negative. When **Sanger sequencing** was the only available method, one or two major syndrome associated genes were sequenced with or without large genomic rearrangement (LGR) analysis. With wider availability and decreasing cost of **multigene germline NGS panels,** the current practice is as follows:

- NGS germline panel testing of 8–100 genes is the default option for majority of cases.
- In cases with characteristic syndromic features of FAP, MEN2, NF1, PJS, etc., sequencing (+/− LGR analysis) of a single gene may be considered if it is cost-effective.
- For classical HBOC or Lynch syndrome, if multigene NGS panel is not feasible or significant psychosocial sequelae with VUS identification is expected in an individual, 1–2 most commonly implicated genes may be sequenced (+/− LGR analysis). In Lynch syndrome, gene/s showing loss of expression in tumor on IHC can be tested.
- Individuals from specific communities with a known founder mutation can be first tested for it before more comprehensive genetic testing, as is done in Ashkenazi Jews.

Genetic testing in a family should start with the person who has the characteristic early onset cancer of the suspected syndrome. If a mutation is identified, relatives at risk are offered testing. In families with suspected hereditary cancer syndrome and no person affected by cancer is alive or available for genetic testing, healthy at-risk relatives can be tested if they wish to know their inherited cancer risk.

Sample for genetic testing: Germline mutation analysis is done on genomic DNA from normal cells, preferably peripheral blood lymphocytes (PBL). Cells from buccal swab or scrapings as well as skin biopsy can also be used. After informed consent, 3–6 mL blood sample is collected in EDTA tubes and transported to the laboratory at room temperature. As mutation in DNA from blood sample of a leukemia patient may have somatic origin, germline testing should be done on buccal swab sample.

Genetic testing and reporting: Known sources of preanalytical and analytical errors should be minimized using standard operating procedures and stringent quality assurance and quality control measures. Possibilities of sample mix up within and between families tested together, or their incorrect identification while interpreting results or reporting should be eliminated. If there is slightest of doubt, results should be confirmed on an independent sample. DNA quality should be acceptable for the sequencing method. In Sanger sequencing, the coding region of the gene/s is PCR amplified with specific primers, the amplified DNA is cleaned of impurities, sequenced on automated capillary sequencers using dideoxy-chain termination method. The output of the sequenced region is in the form of chromatogram. With NGS based multigene panel testing, the genomic DNA is fragmented, the region of interest of the genes in the panel is enriched or captured with various methods, amplified and then sequenced using Illumina or other NGS platforms. The raw data generated is checked for quality and special bioinformatic algorithms are used for data interpretation and variant calling. Any variant identified in the sample is compared with existing databases and ClinVar to ascertain is pathogenicity and reported using the five-tier system, using the HGVS nomenclature as described earlier [10, 12, 13]. Benign or likely benign variants are not reported and any pathogenic or likely pathogenic variant identified is reported, with brief explanation of why it is considered pathogenic, and its association with caners in the tested individual and their family. Extended family testing is offered and cancer prevention measures are recommended in mutation carriers. VUS reporting practices are very variable with few laboratories not reporting any identified VUS, some reporting VUS only for the genes implicated in the suspected syndrome, while others report all VUS in the genes included in the panel. Periodic or continuous variant reclassification program should be done by the testing laboratory and the referring clinician should be informed whenever a previously reported VUS has been reclassified as likely benign or pathogenic.

8 Cancer Screening and Prevention

Cancer genetics programs aim to reduce cancer morbidity and mortality in cancer prone families by genetic counseling, genetic testing and cancer prevention and screening advice to mutation carriers. As large cohorts of healthy carriers of specific gene mutation carriers have not been followed up for decades, level 1 evidence for survival benefit with most of the screening and prevention methods is not available. These recommendations by the NCCN, ASCO and other professional societies are therefore based on:

1. Age and gender specific cumulative risk for a cancer in mutation carriers (Table 3) to ascertain if the risk is high enough to institute high-risk screening and prevention from a certain age.
2. Sensitivity and specificity of various clinical, endoscopic, radiological or biochemical methods for early detection of the syndrome associated cancers.
3. Effectiveness, toxicity, acceptability, cost and compliance of nonsurgical and surgical methods for cancer prevention, ideally with long term data on all-cause mortality and quality of life.

Surveillance or high-risk screening for cancer risk in various organs has been previously described [54, 55] and summarized in Fig. 3. Clinical examination can detect early cancers and precancers of the skin and compliment radiological or biochemical evaluation of thyroid, breast, CNS and bone soft tissue tumors. Radiological evaluation with MRI, CT, USG, Mammogram, as appropriate, is useful for screening for breast, CNS, bone soft tissue, prostate and intra-abdominal tumors, but is of limited value in ovarian cancers. Laboratory tests with tumor markers like PSA, calcitonin, plasma free and urinary metanephrines, fecal occult blood and few other tests are useful for screening of some cancers (see Fig. 3). Endoscopy is the main screening method for lower and upper GI cancers. The age for initiating screening and the combination and frequency of screening methods is based on the age specific cumulative risk of a cancer, its natural rate of progression and how different diagnostic methods complement each other.

Chemoprevention using tamoxifen, raloxifene or aromatase inhibitors can almost halve the risk of BRCA2 associated ER+ breast cancer [56] but its use remains low due to some uncertainty regarding the risk benefit ratio with its long-term use. The chemoprotective effect of high-dose aspirin (600 mg daily) for colorectal cancers in Lynch syndrome has been clearly demonstrated in the CAPP2 randomized trial [57], but it is not routinely used, with the CAPP3 trial yet to report whether lower doses would also be chemo-preventive.

Risk-reducing surgeries for specific cancer risks are considered in absence of highly sensitive and specific screening methods as in ovarian cancer; or despite screening, most detected cancers require toxic or morbid cancer therapy, e.g., stage 1 TNBC, colorectal or medullary thyroid cancers as in BRCA1, APC and RET gene mutation carriers. Bilateral or contralateral nipple and skin-sparing risk-reducing mastectomy (RRM) with reconstruction can reduce breast cancer risk to <1% and reduce breast cancer mortality but is associated with significant complications and its impact on overall survival is yet to be demonstrated [58]. These aspects should be discussed in detail for an informed decision process. Bilateral risk-reducing salpingo-oophorectomy is strongly recommended after the age of 35 years if child bearing is complete with 1–2% residual risk of primary peritoneal cancer. In APC carriers, when endoscopic management is not feasible for the extent and nature of polyps, prophylactic total procto-colectomy with ileal pouch anastomosis or more extensive resection with colostomy is considered [59]. The American thyroid association recommends ages for RET genetic testing and prophylactic thyroidectomy as per risk

	*CANCER SCREENING OR SURVEILLANCE RECOMMENDATIONS				**CANCER PREVENTION OPTIONS

level of the mutation to minimize the risk of metastatic incurable MTC [60]. Prophylactic thyroidectomy is recommended within first year of life in MEN2B codon 918 or 883 mutation carriers and in the first 5 years of life for MEN2A-associated codon 634, 620, 618 or 612 mutation and only screening or delayed thyroidectomy for other less penetrant mutations. Any risk-reducing surgery should be performed after extensive counseling regarding the pros and cons and available option. Long-term follow-up to identify and manage quality or life and survivorship issues should be adequately addressed.

9 Conclusion

The significant burden of hereditary cancer often goes unrecognized, and these families are underserved. Using a conservative estimate of 3% of all cancers being hereditary, India would have ~50,000 hereditary cancer cases annually who will require comprehensive clinical and laboratory genetic services including specialized counseling for cancer prevention and appropriate treatment. There is a need to develop culture sensitive counseling methods and generate level 1 evidence for clinical benefit for the currently recommended screening and preventive measures and develop more effective and acceptable methods. The rapidly increasing indications of genetic testing have led toward the move for mainstreaming of genetic testing, for which the practicing oncologists should acquire essential knowledge and skill.

1 Introduction

Medicine is an information intensive field. Patient care, research and education are three important aspects of medical domain and exist together. No education is possible without clinical work, and medicine cannot progress and medical knowledge cannot expand without the rigors of research. These aspects are inextricably intertwined and are highly information dependent. The experts are involved in all three activities—clinical, research and academics, of which the latter two result in writing, publishing or presenting at academic gatherings and may drive policy-making decisions. Clinicians need to stay updated in their field to be able to provide the best advice and healthcare to patients. Heath care is driven by two major forces—updated information and continually changing technology. In oncology, the challenges of healthcare and research are multifold. Management of cancer has holistic approach. A team with varied expertise, including nutritionists, and medical social worker have joint approach towards medical care for the patient, hence the same information has various applications and usage.

The decade of 2000, experienced huge proliferation of information communication technology (ICT) and Internet. Wide proliferation of web resources brought a sea change in the collection and dissemination of information. The technology in general and specifically Internet has not only expanded the base of information resources but has significantly changed the way information is searched and accessed. With immense technological advancements and its appropriate applications like—database integrations, mobile apps, several types of search and discovery tools, increased the ease of accessibility to information, causing a significant shift in the way doctors' source clinical information [1]. The pressing need for recent information and evidence-based practice ensured that the Internet became an essential tool as it contains the most up-to-date information in vast quantities [2]. With continuous expansion in medical knowledge, it is challenging for doctors to keep abreast of the latest evidence and therapeutic recommendations. This challenge is particularly high for residents, since as junior doctors, they do not have the experience and knowledge base of their seniors [3]. Electronic or online resources, due to their ease of availability and accessibility on various devices, are most preferred by clinicians [1–4]. This digital mobility of information through various channels makes it incredibly easy to access information from anywhere and on variety of devices. Information and technology literacy are, therefore, necessary to determine what is important in the context of the need.

2 Growth of Literature

It was predicted that by 2020 more than 40 zettabytes (or 40 trillion gigabytes) of digital data would be generated and termed as 'data deluge' by data scientists. It is expected that more than 2.5 million scholarly articles will be added every year to already existing bank of about 50 million scholarly journal articles [5]. The ever-growing volume of literature has made it impossible to effectively search and keep pace with reading. The growth of electronic media, networked information and proliferation of web not only changed the way in which information is queried and sought but also democratized the end users. Medical literature is also growing by leaps and bounds. PubMed indexes more than 35 mil-

lion articles from about 5000 biomedical journals [6]. Oncology is a rapidly developing field with a growing number of publications every year. A quick PubMed search for Mesh Term 'Neoplasm' without assigning any limits resulted in 3,024,268 citations. Several informal channels also generate information like hospital generated data both in printed and multimedia formats, viz., electronic medical record (EMR), audio visual formats (teaching pathology files, surgical videos), raw data, blogs, personal communications (written and verbal), unpublished reports like research reports and several other sources, which are not indexed and difficult to locate. Answers to information needs may also be embedded in these sources and are often referred.

3 Information Needs

Information needs of clinicians can be categorized as related to clinical or service and academic and research. These are of varied types and complicated and are made at various settings—private practice, critical care, etc. and which may or may not be expressed. These information needs of clinicians are rarely simple, time bound and are associated with day-to-day work, related to various aspects of patient care like challenging diagnosis, treatment decisions or unexpected complications, lack of self-sufficiency and or gaps in the current knowledge, or are sought for future use. Inability to answer patient specific questions with general resource, difficulty and locating appropriate information often led to doubts, if the information really existed as ready to use material. Some needs are immediate while some may be long term with constant need of periodic updates on a particular topic. Decision making, seeking new ideas, opinions, solution to a particular problem, data validation, academic need, answers to queries raised by colleagues, peers or patients, research related or long-term unanswered issues are few of the factors that raise information needs and queries. Clinicians need rapid access to concise answers that are easy to find and help in decisions and actions [7]. The queries may be self -initiated or posed by colleagues or patients, although answers to all queries may not be pursued.

Information is mainly sought for gaining current knowledge, updates, solving problems, validating, clarifying doubts and similar matters related to domain activities. Clinicians not only require comprehensive but also look for critical appraisal of the medical literature and with many points of view. Jerome demonstrated that many questions require representation of more than one viewpoint for holistic view and complete answers [8]. Information needs in oncology are complex and dynamic, due to multidisciplinary approach to cancer care. An evidence-based work culture among the clinicians has given rise to need and search of information with different perspective.

A study observed that onco-physicians reported to have at least one question for every four or five patients. While in outpatient primary care setting, it was observed that on an average, about two clinical questions were generated for every three patients, and higher numbers reported in the inpatient teaching setting [9]. It is observed that answers to all questions are not searched.

In a user session of the biennial KRM seminar, the clinicians narrated their varied experience in obtaining necessary information while preparing their articles, reports and theses. Some of the challenges identified were: inadequate hands on training to handle the digital resources, unavailability of patient records online and within library, search ability and accessibility to institutional old publications, very little data on Indian cases, non-availability of full text of articles and few technological challenges like weak connectivity to internet [10].

Information need is often clubbed with published literature and real time clinical data from patient health record (EMR) and factual information to serve both clinical and academic/research information needs. Information needs for academic and research activities are different from that of clinical queries. In a clinical setting, the need is patient oriented, situational and personalized toward patient, hence the timely need of precise information. The need for precise and ready to use quality materials is required in evidence-based approach to support clinical decisions.

4 Example of Clinical Query

Topic: use of Botox in patient with total laryngectomy for voice rehabilitation

Context: Patient care—quality of life (QOL)

Background: Patients who undergo total laryngectomy loose voice completely. Patients' speech is then assisted by machine, which is not very comfortable, has poor clarity and affects the quality of life. A research outcome for patient who undergo this treatment and their voice quality was observed and conduct similar study in-house.

Information needs: (1) Background information, clinical trials publication, research publications in journals; (2) Information in Indian context. So, what was required, is a literature search for published information on above query and its outcome with emphasis in Indian context. While discussing with clinician (a typical reference interview), it was observed that comparative information was also required.

Books were referred to collect background information; journal articles were searched in PubMed, and IndMed and MedInd. The last two resources are databases for articles published in Indian journals. The purpose of **IndMED** is to index selected peer reviewed Indian medical journals, while MedInd is one-point resource of Indian biomedical literature covering full text of **IndMED** journals.

Research and academic activities require high volume of information. Information is sought on a research question, hypothesis formulation, what is reported, active researchers and also factual information, which depends upon the type of research being planned or conducted. A typical clinical trial will need information specific to the problem, while an academic research in part fulfillment of degree may not need focused information, but as the research progresses, the need may shift to pointed questions. Academic needs may be related to teaching, conference presentations, writing books, research papers, reviewing activities or preparing for examination.

5 Example for Research Need Query

Topic: A study on pain management and perception of pain by patients

Context: Writing a study report

A study was conducted on pain management and patients' perception of pain. The objectives of the study were perception of pain by patients because of (a) side effects and (b) actually due to disease. The study sought to examine cultural and ethnic influences on perception of pain, easy addiction to analgesics and whether patients perceived complaints to primary physicians as a waste of consultation time or a distraction from the main focus on the disease. The study was questionnaire based.

Information need: what is reported and comparative information and information in Indian context.

Searches: PubMed, Nursing database, MedInd and IndMed were searched, but did not yield good results. Search was further supplemented using Google scholar. Few references in non-medical and nursing journals were found. The full text of few related articles was obtained through cited references.

6 Patient Education

Oncologists routinely educate patients and address individualized information needs on variety of topics during consultations, to enable patient's informed participation in decisions regarding disease management [8]. The information leaflets distributed to patients are informative about their disease, but may not address practical questions like "what if/incase of" situations [11–13]. Health awareness amongst consumers and patients is rising in India, and patients' approach to libraries for reading materials has also risen. Several resources, websites and information embedded within commercial resources, are available that can help in creating 'made to request' information material. Collaboration between clinician and librarians can support such needs. 'Medline Plus' of NLM addresses consumers and patients' health information needs. Awareness of availability of ready resources and its consultation is essential amongst clinicians. The diagnosis and treatment of cancer can present a major challenge to patients. Fears of longevity, tests and treatments, side effects of treatment, difficulties in adjusting to physical changes like body appearance and functioning, social disruption, financial concerns and religious beliefs are some concerns that have to be addressed through education. Although it is known fact that patients use Internet for information, they prefer to receive personalized written information from their health care provider, and medical humanities plays an important role in cancer management [11–13].

7 Preferences of Sources and Searching

A routine in-house survey observed that oncologists preferred e-journals. A survey of oncologists in Mumbai city also indicated the same and observed that preferences for e-journals [14] were based on authenticity and currency of information with easy and quick accessibility. Searching online journals for research articles was the first choice rather than systematically searching e-databases. Often there is a need to refer to various resources at a time - subscribed resources, web-based free resources and in-house generated resources like EMRs, cancer registries and scientific reports to answer complicated queries. The requirement to refer individually or combination of these resources at a time, depends upon the purpose for which the information is sought. Linkages to these varied sources with single point search and access are the need of the hour, and hence discovery tools or web scale information search engines are in demand. Common search interfaces, common search windows or federated searches are therefore often found on library webpages.

The electronic journals were highly impacting resource, especially in medicine. However, a shift on preference of sources has been observed during past few years. Oncologists are more confident searching scientific databases [15]. The information needs of oncologists significantly differ from the other medical experts and have different ways to access specific information [16]. The information support for whatever purpose is proportional to the user's awareness of resources, searching skills and library services.

Clinicians and specially residents are unaware of search techniques, digital resources and do not observe libraries as service providers and gateways to information. Time constraint, uncertainty, peer support and unable to locate appropriate source are some of the reasons for not seeking answers to all questions [15, 17]. Background knowledge of search tools and strategies, usage of resources and comfort level with technology decide on how clinicians identify and respond to information gaps [17].

Literature search is a daunting task and the challenge of searching, locating and quick delivery of document is immeasurable. Many physicians have concerns about finding of the right resources and identifying the authoritative resource on the web [15]. They fear searches would result in too many or too few citations, or irrelevant articles, causing loss of time.

An effective searching depends upon three components, viz., appropriate database/resource selection, domain knowledge and search technique and skills. Information search is an essential component of the research process. A review of the literature on a specific topic or clinical question is crucial for academic study and professional development, to create and publish secondary analysis on a specific topic. Asking the right answerable question and appropriate resource selection is key to searching appropriate and relevant information. A broad question will give too many results, and manual filtering would be tedious. It is therefore necessary to first understand the nature and purpose of the information query. The purpose directs the selection of the resources. Information queries can be categorized as back ground questions and foreground questions. Answers to background questions are usually found in medical text books, handbooks or resources like point of care tools—first consult, or descriptive or narrative reviews which take an overview of the topic over a period of 5–10 years. Answers to foreground questions are usually found in secondary information resources which provide availability about and accessibility to information, that is an abstracting and indexing resource or databases like Medline, PubMed, EMBase, CINAHL and Cochrane (systematic reviews), ACP Journal club and other synthesized resources. It is always better to begin a search using a database when we are looking for foreground information, as it saves time and searching across several journals is easier.

Information is flowing in from all quarters, and in all forms and formats. Information overload is overwhelming and handling it is difficult if searches are not planned properly. Effective searching has always been a challenge to clinicians' especially junior doctors, as they are not exposed to search techniques and search skills. Ely identified about 59 obstacles encountered by clinicians, viz. [18] difficulty in modifying original question, open questions, difficulty in selecting an optimal search strategy; failure in topic coverage by seemingly appropriate resource; uncertainty about how to know when all the relevant evidence has been found and stop the search and inadequate synthesis of multiple bits of evidence into a clinically useful statement.

It is observed that information resources supported clinicians' needs related to patient care—diagnosis, choice of drug, etc. and enabled better informed clinical decisions and impacted patient care [19]. Strategic planning and a little homework prior to searching help in addressing these difficulties and conducting an effective search. Understanding the requirement and selecting appropriate resource sets the stage for a good search. A methodical approach in formulating a query that the system understands will ensure good and relevant results. A strategic planning will consist of answers to the following questions, as preparation for search.

- What is that I am looking for (i.e., finding the focus of the question)?
- What are the key concepts (ideas) embedded in the question?
- What do I know about these concepts (i.e., understanding of these concepts)?
- What are the alternative and variant terms that describe each of these concepts?
- Where do I start searching?

It is not enough to know the resource, but it is more essential to know the appropriate one, and how to use it effectively. There are several resources and each one is focused - domain and information format (see Table 1 for key resources for oncology and Table 2 for guidelines). Searching is database structure dependant. Pre-requisites required for effective searching are domain knowledge,

Table 1 Useful resources

Purpose/Utility	Resource	Operators used	Proximity operators used
Citation searching—Biomedical and medical	PubMed, Medline	AND, OR, NOT	None
	OVID—Medline, OVID—Psychinfo	AND, OR, NOT	NEAR, FREQ
	EMBase	AND, OR, NOT,	NEAR/n finds words near within no. of word on both sides NEXT/n—within 'n' words of each other
	Web of Science	AND, OR, NOT	NEAR—Nx X = upto 15 word
	SCOPUS	AND, OR AND NOT	WITHIN—W/n Preceded by—Pre/n $N = 0–225$
	MedInd	–	–
	IndMed	AND, OR, NOT	–
Citation searching—Nursing	CINAHL	AND, OR, NOT	NEAR—N/x WITHIN—W/x
EBM resources	Cochrane systematic reviews	AND, OR, NOT	NEAR within = 6 words of each other NEAR/X, X = no. of words within each other NEXT—words next to each other like ADJ
	BMJ best practice

Table 3 Connectors/operators and their use

OR	**AND**	**NOT**
 A OR B Will retrieve citations with terms ‘A,’ ‘B’ and ‘AB’	 A AND B AB = cancer **AND** women	 A NOT B Citations with only the term ‘A” retrieve citations—**‘A,’ neither ‘AB’ nor ‘B’**
• Hamburger OR eggs OR Both terms in citations • Nutrition OR diet OR Both terms in citations	• Toxicity of Lead—Lead AND Toxicity • Calcium in women—Calcium AND Women • Nutrition for Infants—Nutrition AND Infant	• Dementia **NOT** Alzheimer’s • Diet **NOT** Vegetarian
NEAR	**WITH**	**ADJ**
Ex.—Research NEAR2 Dyslexia Tells the data base to search the two terms within in vicinity of 2 words in between	**Ex**.—Effect WITH Effluent The two terms have one word in between and in the same sentence	**Ex**.—Curcuma ADJ Longa The two terms have to be next to each other without any other term in between and the order is as typed

appropriate selection of database/resources and knowledge about the search interface.

Once keywords, or key-terms or descriptors are identified, small search statements are made on the databases for each concept and finally all search statements are combined using Boolean logic and presented to the system, which shows final results. These statements or keywords are combined using ‘connectors’ called Boolean operators (logic)—AND, OR NOT in most databases (PubMed, MEDLINE, CINHAL, etc.). The AND, OR NOT have specific role to play in the search statement. They either broaden the search results, narrow and limit the search or eliminate a particular aspect in the search query. Many databases like Biological Abstracts may also include other types called proximity operators, viz., NEAR, WITH and ADJ. These are usually used to indicate the appearance of related keyterms/words in literature and help on focusing on the terms (Table 3).

Building search strategy is like building a wall, where terms are bricks and ‘connectors’ are adhesives. When there are complex queries, break query into concepts, search key term/descriptors/keywords for each concept independently and then combine all statements using operators for final results.

8 Summary

- Boolean operators are used in PubMed, CINHAL, MedLine, EMBase and Cochrane
- AND is used to connect concepts when both or all must be present
- OR is used to group synonymous terms when at least one must be present
- NOT is used to eliminate articles containing the specified term.

PubMed is the key database for all medical and biomedical literature. This is the first database to go to incase of information need. Along with Boolean operators, PubMed interface where all databases fields are searchable and can be combined using Boolean operators and the search results can be further limited by age, gender, type of studies, format of document like review, case report, years of study, etc. within the databases combine searches to refine the search results. Apart from being a strong database, its strong indexing system and use of Medical Subject Heading list (MeSH) to index, tag and classify the citations within Medline database helps in focusing searches. Mesh terms can be used to select citations based on their focus of discussion. Since PubMed/Medline are the most appropriate database for searching medical literature/citation, the following examples are in context with searching PubMed, in order to provide an idea on the searching technique, skill and use of database features. Although the description and examples are from PubMed, most databases in medicine use MeSH and follow the same search heuristics perhaps with slight variation. These simple heuristics of searching can help in formulating appropriate search statements and effective results.

9 Example of Search Strategy (PUBMED) Using Boolean Operators

Topic: Publication on use of TRAM flaps in plastic reconstruction for breast cancer patients

Concepts: Flaps, Breast cancer patients, Reconstructive surgery

Search strategy

#1 TRAM flaps [ti/ab]

#2 Reconstructive surgical procedures [MeSH]

#3 breast cancer [ti/ab]

Combine above statements—#1 AND #2 retrieves 143 citations

Combining #1 AND #2 AND #3, retrieved 40 citations on PubMed

In the above search, the statement indicated to the database to search ‘TRAM flaps’ in title and abstract field, so that focus is maintained and the MeSH terms were used for “procedures” to ensure the discussions were about the procedures in the articles. It is essential to note that all boolean operators and proximity operators are always presented in Capitals and must not be used as English language conjugations.

10 Evidence based Medicine

Searching for evidence-based medicine needs tools to formulate query and are also used for forming search strategy, viz., PICO and SPIDER, of which PICO is very popular.

PICO stands for **P**opulation, **I**ntervention, **C**omparison and **O**utcome.

Stages in search:

- Identify key concepts using PICO.
- Determine alternative terms for each concept.
- Define search dates, study groups, etc.
- Formulate a final search statement, using Boolean logic.

Other tools, like PICOT (where T is the period of data collection) and SPIDER (Sample, Phenomenon of interest, Design, Evaluation, Research type), are usually recommended for searching qualitative and mixed research methods. However, PICO is most common and highly recommended tool. In effect, these tools help us to break our need in to different components and helps us to focus on the actual information need. Once the focus of question is identified, the next step is to identify keywords, and alternative words for each concept, and lastly help us to identify appropriate resource.

11 EBM Example

Results of phase III clinical studies (interventional/of drugs) conducted in patients of platinum resistant ovarian cancer (results published in the last 5 years) (Figs. 1 and 2).

P = Patients with resistant ovarian cancer

I = drugs

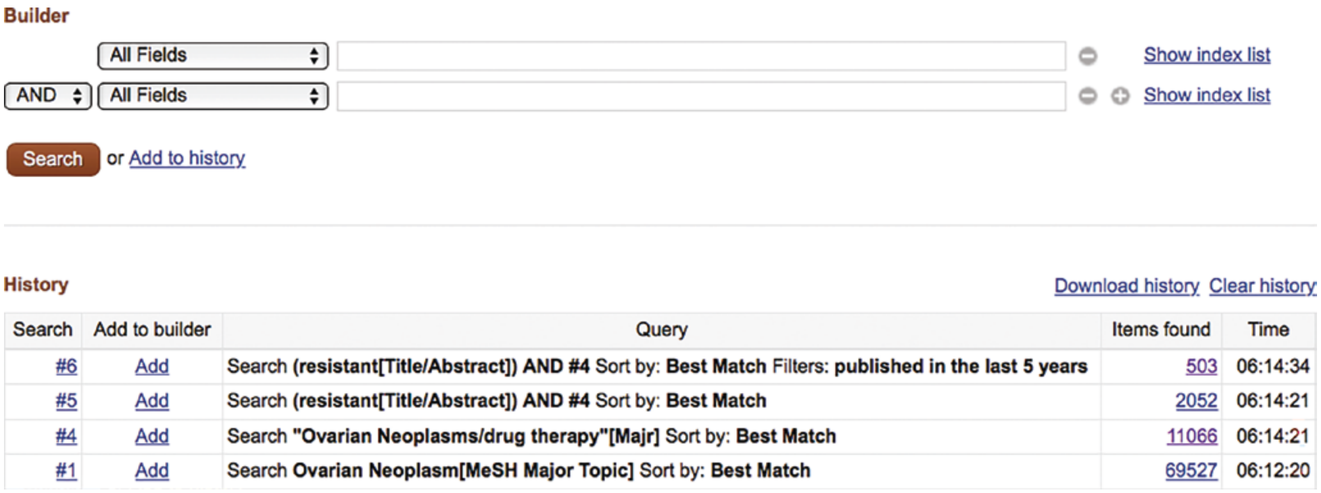
C = platinum resistant

O = effectiveness

(Ovarian neoplasms [MeSH]/Drug [Majr]) AND (resistant [Title/abstract])

Resource used—PubMed., Cochrane, PubMed Clinical Queries

Cochrane library consists of four databases, of which systematic review database is a collection full text of systematic reviews of randomized clinical trials, i.e. analysis of the results using statistical synthesis of data (meta-analysis) to establish evidence.



Search	Add to builder	Query	Items found	Time
#6	Add	Search **(resistant[Title/Abstract]) AND #4** Sort by: **Best Match** Filters: **published in the last 5 years**	503	06:14:34
#5	Add	Search **(resistant[Title/Abstract]) AND #4** Sort by: **Best Match**	2052	06:14:21
#4	Add	Search **"Ovarian Neoplasms/drug therapy"[Majr]** Sort by: **Best Match**	11066	06:14:21
#1	Add	Search **Ovarian Neoplasm[MeSH Major Topic]** Sort by: **Best Match**	69527	06:12:20

12 Staying Updated

The most important need and challenge for clinicians is staying updated in their domains. It is humanly impossible for any individual to read the voluminous literature and assimilate the knowledge. The information is generated and made available on several formats and search platforms. Several trials conducted across the world, add to the knowledge base of about potentially effective treatment. To keep a hawk's eye on the new developments no matter how niche the domain is, is humanly impossible. Almost all resources provide 'alerts' on chosen topics, or 'table of contents' (TOC) as e-mail services. Several web-based information systems are also available, and many individual institutions have invested in federated search or discovery tools and artificial intelligence systems to seek answers, where user profiles can be generated to stay updated.

PubMed search statements can be saved and set to receiving alerts as email every time new citation is added to PubMed through 'My NCBI' account. Subscribing to RSS feed is another way to receive updates in mailbox.

Information is gathered and stored for use, reuse, recycle and regeneration. Gathering of useful citations is like creating your own library for present and future use. Managing collections of citations and articles is therefore equally important. Use of citation management tool from the beginning is recommended. There many free and subscribed citation management tools. These are embedded in Word processing software and operate on all browsers, which help in auto-downloading of the citations and easy to insert citations in manuscript in the preferred format and style effortlessly.

Libraries in digital scenario are gateway to information and strive to make e-resources available and accessible at one search. The libraries not only update collection but also adopt new supportive technologies and are trained in search and retrieval. Medical librarians can substantially support information needs related to clinical questions or academic queries. They have diverse roles apart from management of electronic resources. They are continuously engaged in user instruction and support clinical research needs and provide information search and retrieval services. When deprived of time, or difficulty in search or locating resources, it is always good to consult library professionals, who can serve as intermediaries and add value not only in identifying appropriate resources but also conduct effective searches. Being digitally literate is necessary and can be attained by reaching out to librarians for an information literacy tutorial and asking for search support. It is a well-established fact that when searches are conducted jointly with medical librarians, the results are more appropriate.

In spite of all preparation, it may happen that search results are not satisfactory. It must be remembered that information search is a reiterative process, and if results are unsatisfactory, a relook at query, concepts, keywords, database selection and statements is necessary.

13 Summary

- Plan your search well.
- Identify concepts or use PICO formula.
- Identify key terms/keywords/descriptors for each concept.
- Choose appropriate database.
- Make search strategies for each concept and run the searches.
- Combine all searches.
- Keep record of search statements, results retrieved.
- Browse, select relevant citations and download/save to citation managers.
- Difficult to locate—consult your librarians.

Oncology Training and Education in India

Siddhartha Laskar, Anant Ramaswamy, Garvit Chitkara, and Shripad D. Banavali

1 Overview

The availability of trained and skilled manpower besides an appropriate infrastructure are important pre-requisites to the delivery of optimal cancer care. Specialty education in cancer diagnosis and treatment has been a mandate of the founding fathers of Tata Memorial Centre (TMC) since the time of its inception in 1941. Sir Nowroji Saklatwala and Mr. JRD Tata encouraged and inculcated the concept of comprehensive cancer care along with education and research. Sir Roger Lumley, the then Governor of Bombay appreciating the vision of the Dorabji Tata Trust, said in his inaugural address '… *You are attacking it on the three fronts of Treatment, Education and Research—all three of them essential and interdependent—I must express my admiration for the completeness of your plan'*.

Cancer care and options for treatment across the stages of cancer have exponentially increased with a surfeit of diagnostic tools and management strategies being available and applicable. After having started in mid-twentieth century, the cancer training programs in India have matured into more focused and specialized courses and train a sizeable number of doctors trained in various facets of cancer treatment. These doctors not only contribute to the cancer care but also take active part in research and education. The total number of cancer cases in the India have steadily increased [1]. Concurrent with the exponential increase in patient numbers, there has also been significant increase in complexities of treatment and an explosion in scientific information that one needs to understand and assimilate. Despite the increase in training programs to address the growing needs of qualified personnel, there is still a big gap that needs to be filled both in quantitative and qualitative terms.

The National Eligibility Cum Entrance Test (NEET) 2020 and the National Medical Commission (NMC) database mentions 18 institutions offering 79 placements for DM Medical Oncology programs, 23 institutions offering 98 placements for MCh in Surgical Oncology and 87 institutions offering 594 placements for MD in Radiation Oncology across the country. Additionally, few deemed institutions like the All India Institute of Medical Sciences (AIIMS), New Delhi and Jawaharlal Institute of Postgraduate Medical Education & Research (JIPMER), Puducherry also have training programs in various specialities of oncology. It is also essential to note that besides the MD/DM/MCh training programs, training in oncology is also offered via the Diplomate of National Board (DNB), under the aegis of the National Board of Examinations (NBE), New Delhi, an autonomous academic body under the Ministry of Health and Family Welfare.

2 Education and Training at Tata Memorial Centre (TMC), Mumbai

Cancer education and training have always been areas of high priority at TMC. The division of academics at TMC was established in 1982 and is affiliated with the Homi Bhabha National Institute (HBNI), a deemed university of the Department of Atomic Energy (DAE), Govt. of India. The courses offered in TMC can broadly be classified into the streams of Health Sciences at Tata Memorial Hospital (TMH), Parel and Life Sciences at the Advanced Centre for

Treatment, Research and Education in Cancer (ACTREC), Kharghar. The institute conducts a wide range of courses recognized by the Medical Council of India (MCI)/National Medical Commission (NMC). The courses include MD, DM/MCh programmes in oncology (e.g., Radiation Oncology, Medical Oncology, and Surgical Oncology) and other related subjects (e.g., Anesthesiology, Radiology, Nuclear Medicine, Microbiology, Immuno-Hematology & Blood Transfusion Medicine, Pathology, Palliative Medicine). Superspecialty courses like DM in Pediatric Oncology, Critical Care, Oncopathology, Interventional Radiology and MCh in Head and Neck Surgery and Gynecological Oncology at TMC have been introduced for the first time in the country.

Besides training programs for the broad and superspeciality subjects, TMC offers post graduate training in subjects like Advanced Diploma in Radiation Therapy (ADRTT), Imaging Technology (ADMIT), Nuclear Imaging (PGDFIT), Nursing Oncology along with Masters courses in Nursing Oncology and Clinical Research. The training program on patient navigation (KEVAT) is unique and is another first in the country. TMC also offers multiple fellowship programs under the umbrella of the HBNI in varied specialities.

The teaching programs include classroom lectures, seminars, bedside clinics, hands on practical training and informal discussions. Significant emphasis is laid on practical training and self-learning. These are considered very significant training components for technical skill development, decision-making abilities, confidence building, coordination and team work.

The Academic Research Program at ACTREC focuses at providing an in-depth insight into diverse areas of Life Sciences with emphasis on Cancer Biology in an attempt to unravel the molecular mechanisms responsible for many manifestations of cancer using in vitro cell line and animal model systems. The Centre has a very active Ph.D. program in Life Sciences under the HBNI. The research interests cover a wide range of topics including areas like mechanisms of carcinogenesis, the underlying genetic changes that could bring about this transformation, mechanisms of disease spread, reasons underlying treatment resistance, the impact of environment and lifestyle, etc. Short-term training spanning 1 to 6 months is offered to students (Bachelor's or Master's) to conduct research as a part of their curriculum under the guidance of principal investigators of the centre in specific areas of Cancer Research. Programs are available for faculty/teachers/staff or doctoral students of academic/research institutions who wish to learn specific techniques. Short observership programs are available for students or faculty of academic or research institutions who wish to observe specific techniques and training opportunities are also available for M.Sc.(I/II) students during their college summer breaks for periods of 1–2 months.

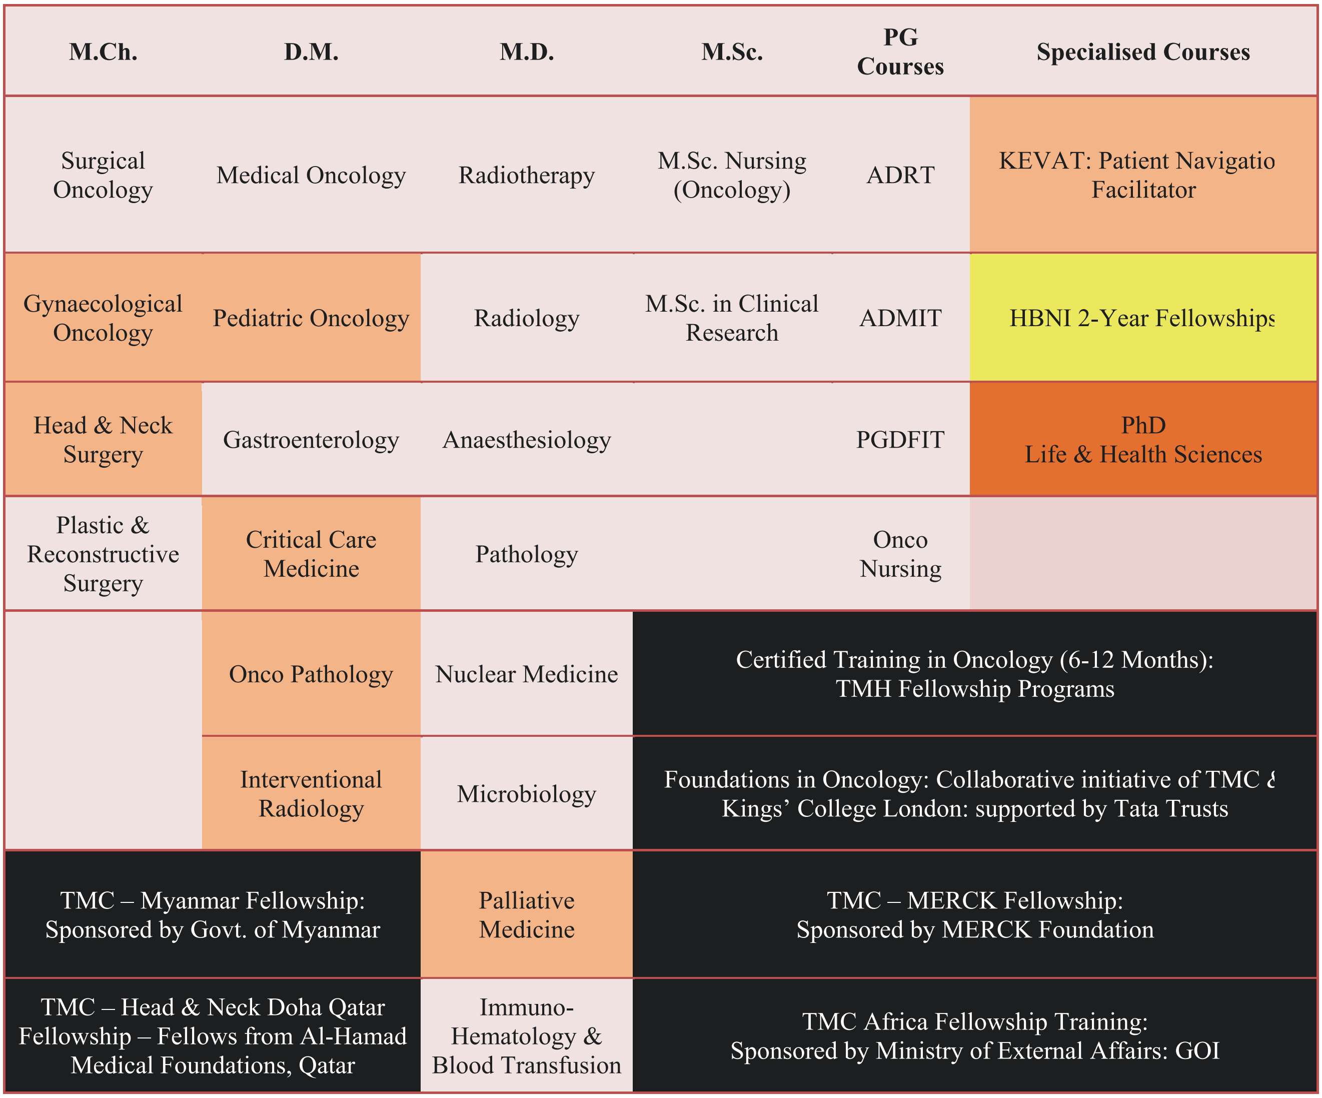
Practical hands-on trainings and workshops that are essential components of training in comprehensive cancer care are regular features of the educational programs in the institution. The ongoing courses at TMC are continuously reviewed for quality and new courses added to address the growing needs.

The Bone Marrow Transplant facility was relocated from TMH to ACTREC in November 2007. Approximately 800 allogeneic and autologous transplants have been performed in ACTREC since then. Since 2009, unrelated donor transplantations and haploidentical transplantations are being routinely performed in appropriately selected patients. There is a social scheme in place for deserving, economically backward patients who have highly curative disease but do not have the finances to undergo autologous or allogeneic transplant. ACTREC offers a 1-year fellowship in BMT for medical oncologists having completed DM and also a 1-year BMT nursing fellowship.

The Proton Beam Therapy Centre at ACTREC is the first state of the art particle therapy facility in the public sector in India. Besides catering to the treatment needs of patients from within the country and abroad, this centre is focused on research aimed at generating robust evidence for optimizing the use of proton therapy in various cancers. Training and human resource development of personnel ranging from clinical oncologists, physicists, technologists, engineers and scientists is another thrust area for this centre.

TMC also conducts training programs for sponsored candidates from State Government Medical colleges, Central Government Hospitals, Public Sector Undertaking Hospitals and Regional Cancer Centres across the country (Table 1). TMC provides training programs and courses for specialists and trainees from the region providing training in the field of oncology and related subjects to doctors and allied specialities.

Table 1 Education and training programs at Tata Memorial Centre, Mumbai



M.Ch.	D.M.	M.D.	M.Sc.	PG Courses	Specialised Courses
Surgical Oncology	Medical Oncology	Radiotherapy	M.Sc. Nursing (Oncology)	ADRT	KEVAT: Patient Navigatio Facilitator
Gynaecological Oncology	Pediatric Oncology	Radiology	M.Sc. in Clinical Research	ADMIT	HBNI 2-Year Fellowships
Head & Neck Surgery	Gastroenterology	Anaesthesiology		PGDFIT	PhD Life & Health Sciences
Plastic & Reconstructive Surgery	Critical Care Medicine	Pathology		Onco Nursing	
	Onco Pathology	Nuclear Medicine	Certified Training in Oncology (6-12 Months): TMH Fellowship Programs		
	Interventional Radiology	Microbiology	Foundations in Oncology: Collaborative initiative of TMC & Kings' College London: supported by Tata Trusts		
TMC – Myanmar Fellowship: Sponsored by Govt. of Myanmar		Palliative Medicine	TMC – MERCK Fellowship: Sponsored by MERCK Foundation		
TMC – Head & Neck Doha Qatar Fellowship – Fellows from Al-Hamad Medical Foundations, Qatar		Immuno-Hematology & Blood Transfusion	TMC Africa Fellowship Training: Sponsored by Ministry of External Affairs: GOI		

- TMC in-house programs
- Programs introduced for the first time in the country
- Ph.D. programs affiliated to HBNI
- Fellowship programs affiliated to HBNI

3 The National Cancer Grid (NCG)

The NCG is an initiative of the Tata Memorial Centre, Mumbai supported by the Department of Atomic Energy (DAE), Govt. of India and the Tata Trusts. It was created to form a union of cancer centres in the country which could provide uniform and high standards of cancer care, follow uniform evidence-based guidelines for management of patients, provide training and education in oncology and facilitating collaborative basic, translational and clinical research in cancer to fulfill the cancer healthcare needs of the entire nation.

Aims and objectives include the following:

- Evolve and implement uniform standard of cancer care across India.
- Offer the state of art services for those afflicted by cancer.
- Create human resources to tackle the rising need of cancer care.

- Gauge the magnitude trend and type of national cancer problem through registry and run appropriate epidemiological intervention studies to prevent cancer.
- Direct cancer research in clinic and laboratory to offer cost-effective solution to cancer in India.

Some of the established educational tools offered by the NCG are as follows:

- Virtual Tumour Board (VTB)
- Online Learning
- Travelling School of Pathology
- CReDO Workshop/Research Webinar

Towards the NCG efforts in quality improvement, the NCG hosts educational programs like Quality Improvement Hub (QI Hub) in collaboration with Stanford Medicine (USA), a leader in educational programs for quality improvement for clinical teams. Such programs are designed at providing the participants with conceptual understanding and experience necessary to respond to quality related problems across a complex environment such as clinical practice settings.

4 Summer School in Oncology

Tata Memorial Centre in partnership with King's College, London and supported by the Tata Trusts have initiated this course for undergraduate students pursuing MBBS and those in their early years of post-graduation after MBBS. The module titled 'Fundamentals in Oncology (FinO)' is aimed at enhancing knowledge, skills and aptitude of medical graduates regarding cancer. It provides the student a comprehensive insight into cancer management thereby enabling participants realize their aptitude and assist students in deciding about a future career in oncology. The module lasts for 10 days following which students are evaluated by experts based on written test and interviews. Usually about 150 students participate in the course from educational institutions across the country, selected by respective deans.

Upon completion of the course, the participants receive a certificate, awarded jointly by Tata Memorial Centre and King's College, London. The top five meritorious students are offered an opportunity to undertake a week of clinical observership at Tata Memorial Centre, Mumbai and 4 weeks clinical observership at Guy's and St. Thomas' Hospital, London.

5 "KEVAT" Patient Navigation Program

In order to addresses the need for a structured patient support system for cancer care that will form a bridge between patients and access to care, the Tata Memorial Centre (TMC), in collaboration with Tata Institute of Social Sciences (TISS) and with support from Tata Trusts, introduced a 1-year (full-time) Advanced Diploma in Patient Navigation (KEVAT), for the first time in India. The patient navigation program is aimed at creating a trained task force to facilitate a patient's journey right from entry to the hospital to follow-up and getting back to normalcy, while also taking care of the patient's the emotional, economic and various other needs in a holistic way.

6 Online Oncology Tutorial Series

As a part of a national programme to train doctors about early signs of cancer, the Union Health Ministry launched its first online 'Oncology Tutorial Series'. This joint initiative of the Tata Memorial Centre, Mumbai and the Government of India uses a digital platform, 'Omnicuris', for education on evidence-based practice of cancer care in the country and to make cancer education and training accessible to everyone across the country.

The course is of seven months duration and is intended for physicians, gynecologists, dentists and medical professionals who are not trained oncologists. It has different modules based on various sites and sub sites of cancer. In its 14 h of comprehensive e-learning, it offers 40 video lectures, case studies, questionnaires and webinar sessions with professional consultants of Tata memorial hospital. At completion of the course, the participants undergo an assessment and receive a certificate of completion.

7 National Knowledge Network (NKN)

National Knowledge Network (NKN) is an initiative by the Government of India aimed at establishing a strong and robust Indian network which will be capable of providing secure and reliable connectivity interconnecting all knowledge and research institutions in the country through a high bandwidth network in order to improve access to knowledge. NKN with its broad capability aims to connect all universities, research institutions, libraries, laboratories, healthcare and agricultural institutions across the country to address the need of collaboration to enrich the research efforts in the country. The network design takes into account the future requirements and new possibilities that this infrastructure may unfold, both in terms of usage and perceived benefits. It will facilitate the development of India's information infrastructure, stimulate research and create next-generation applications and services. NKN is a significant step which is designed to enable scientists, researchers and students from across the country to work together for advancing human development in critical and emerging areas.

8 Oncology Training for the Future

There is an increasing demand for precision and personalized medicine in oncology [2] and very much like no two patients, no two cancers are similar. Increased use of Genomics, Proteomics and advent of many other similar technologies have made oncology a very dynamic and constantly changing branch of medicine. With the constantly changing therapeutic options in medical, surgical and radiation oncology, it is important for training also to keep changing accordingly. The following are a few aspects that will need to be added to the current oncology training to keep up with the changing face of oncology.

8.1 Genetics

Owing to the development in the field of genetics and increasing involvement of genetics in prevention and treatment of cancers, it has become utmost important for any oncologist, medical, radiation or surgery to have a basic knowledge of cancer genetics. Any cancer training course would be incomplete without an understanding of genetics in the future.

8.2 Research

Although the current training schedules encourage students to get involved in various research activities, it is necessary to have a dedicated curriculum for protocol development and conducting basic and clinical trials so that cancer treatment can progress in our country to match the standards of the western world.

8.3 Sub-specialization

What seems like an obvious next step of metamorphosis of oncology training to move away from the general oncology training and towards a more site specific, organ-specific cancer training as that would help the students to excel in oncology of one subsite, is not an easy decision. While the organ-specific 'only' training will help the students excel, it will come at the cost of having fewer 'general' oncologists, which is the current demand of the country. As per a report published, India has an oncologist density of 1 for one million population [3] and 1 oncologist for 2000 patients [4]. Hence, continuing to train trainees in general oncology may be the need of the hour, but a site-specific oncology training is the need of a near future.

8.4 Mentor/Mentee Program

Owing to the mental dexterity of the course, it would be useful to include a formal mentor / mentee program in the oncology training as a strong mentor mentee program has shown to improve productivity and student satisfaction [5] and is important for successful professional development [6].

Finally, there is a definite need for harmonization of cancer education and training across the country in order to achieve the ultimate goal of delivering quality cancer care to patients across the country by qualified and appropriately trained personnel.
